Key words: location choice, immigrants and ethnic residential segregation

Abstract

The initial settlement behaviour and the subsequent mobility of immigrants who arrived in the Netherlands in 1999 are examined using rich administrative individual data. The study considers the settlement patterns of immigrants from various countries of origin who entered the country as labour, family or asylum migrants. The evidence suggests distinct settlement trajectories for asylum and other non-western immigrants. The presence of co-ethnics and members of other ethnic minorities, but also socioeconomic neighbourhood characteristics, appear to play an important role in determining location choice. Differences in the settlement and spatial mobility patterns of immigrants with various degrees of distance from the native Dutch in terms of human and financial capital, proficiency in the relevant language(s), and religion confirm the main predictions of spatial assimilation theory.

This research is supported by the Netherlands Organisation for Scientific Research (NWO), VICI grant no. 453-04-001. The paper is part of a joint project with Statistics Netherlands; we are grateful to the Department of Total Statistics for allowing us the use of the Social-Statistical Database. We thank two anonymous reviewers of this journal for their helpful comments.

INTRODUCTION

Ethnic residential segregation is at the top of the social and political agenda in both old and new immigration countries. While residential segregation takes a prominent position in the research agenda in the US, for European cities research on segregation is scarce. Correspondingly, the segregation literature has been dominated by studies considering the residential segregation of blacks and Hispanics in the United States (SOUTH *et al.*, 2005; QUILLIAN, 2002; CUTLER *et al.*, 1999; BORJAS, 1998; SOUTH & CROWDER, 1998; MASSEY *et al.*, 1994; MASSEY & DENTON, 1993). The small scope of research on ethnic segregation in European countries is possibly the result of the relatively low levels of ethnic segregation and the small number of mono-ethnic areas (MUSTERD, 2005).

The high concentration of ethnic minorities in certain geographical locations is widely and implicitly believed to impede the integration of ethnic minorities in host countries. Ethnic segregation is usually associated with a simultaneous concentration of educational failure, welfare dependency, low labour force participation, poverty, crime, and hopelessness. This association has raised public concern about segregation. Consequently, there is a growing interest from policymakers and scholars as some European cities continue to segregate and ethnically related violence has started to appear in some European cities such as London, Paris, and Amsterdam. Although the level of segregation and its interaction with socioeconomic factors has been studied for some European countries (MUSTERD, 2005; BOLT & VAN KEMPEN, 2003; ANDERSSON, 1998), little is known about the role of the location choices of new immigrants in the emergence or continuation of segregation.

Previous studies on the location choices of immigrants have investigated either their initial settlement behaviour or their internal mobility, but seldom both together. This is probably the result of the lack of appropriate data and methodological difficulties associated with having to

1
2
3 use cross-sectional data. These studies have mainly sought answers to the question whether
4 immigrants' location choices are determined by economic prospects and welfare generosity
5 (BARTEL, 1989; ZAVODNY, 1999; BEENSTOCK, 1997; ASLUND, 2005). In that
6 research, the spatial absorption of immigrants and the economic impact of immigration were
7 the central themes rather than the contribution of recent immigrants to ethnic segregation.
8 This paper studies immigrants' settlement patterns upon arrival and their subsequent mobility,
9 with an emphasis on ethnic residential segregation in the Netherlands, utilising a unique
10 administrative longitudinal data file housed by Statistics Netherlands. It is argued that an
11 analysis of initial location choices is only of limited significance in identifying the
12 contribution of new immigrants to ethnic segregation, because the spatial mobility of
13 immigrants tends to be substantial in the first years following arrival.

29
30 New immigrants to the Netherlands are a heterogeneous group, consisting mainly of family,
31 asylum, and labour migrants. These categories of immigrants have different spatial settlement
32 patterns induced by the presence of co-ethnics, housing market restrictions, and
33 socioeconomic status. The location choices of family migrants are probably related to the
34 residential locations of their family members, while the settlement behaviour of other
35 immigrants is likely to be more sensitive to their socioeconomic position and local economic
36 prospects. In addition, the highly regulated Dutch housing market significantly restricts the
37 voluntary character of location choice, given the relatively weak social economic position of
38 immigrants. We have considered institutional restrictions and the strong heterogeneity in the
39 immigrant population. Relying on evidence from the location choice literature, the study
40 explores the role of co-ethnics and other ethnic minority groups in the neighbourhood as well
41 as such economic factors as average wages and unemployment on local labour markets. This
42 approach reveals a stratified settlement and mobility pattern across immigrant groups by
43 country of origin and migration motives.

1
2
3 The study uses the neighbourhood as the spatial unit in which the concentration of non-
4 western ethnic minorities is measured, since the neighbourhood is supposed to be an
5 appropriate delineation of the spatial area in which to investigate the spatial mobility of
6 immigrants (LOGAN *et al.*, 2002; QUILLIAN, 2002; SOUTH *et al.*, 2005). Initial location
7 choices are analysed for immigrants categorised according to country of origin and migration
8 motive (namely labour, family, and asylum migration) by regressing the number of new
9 immigrants arriving in neighbourhoods in the Netherlands in 1999 on the characteristics of
10 the neighbourhoods. These characteristics include the presence of co-ethnics and other ethnic
11 minorities. Evidence of the spatial distribution of immigrants suggests that new immigrants
12 tend to settle primarily in certain neighbourhoods of large cities where their co-ethnics are
13 concentrated. The subsequent mobility is examined using individual data. The propensity to
14 move to less or more highly segregated areas is studied, using three distinct levels of
15 segregation defined by clustering neighbourhoods into *native*, *mixed*, and *segregated*
16 categories based on the levels of concentration of non-western ethnic minorities. These
17 empirical analyses provide evidence for the determinants of mobility into and from segregated
18 neighbourhoods across ethnic groups.

42 PREVIOUS RESEARCH AND HYPOTHESES

43
44
45 Empirical studies on the location choice behaviour of immigrants usually focus either on the
46 location choice upon arrival (ZAVODNY, 1999) or on their migration patterns in the host
47 country (MASSEY *et al.*, 1994; NOGLE, 1994; BEENSTOCK, 1997; SOUTH *et al.*, 2005).
48
49 Only a few studies combine immigrants' initial location choice and subsequent mobility in a
50 longitudinal perspective (BARTEL, 1989; BEENSTOCK, 1997; ASLUND, 2005). The
51 literature suggests that the presence of other immigrants is the primary determinant of
52 immigrants' location choices. Local labour market conditions and welfare generosity seem to
53 play a minor part in determining these choices (BARTEL, 1989; ZAVODNY, 1999;
54
55
56
57
58
59
60

1
2
3 BORJAS, 1998, 1999; KAUSHAL, 2005; ASLUND, 2005). The tenor of the location choice
4
5 literature is that the propensity to migrate varies directly with education and inversely with
6
7 age. Highly-educated immigrants are much more mobile and dispersed and have smaller
8
9 probabilities of migration towards highly segregated areas. Furthermore, within the United
10
11 States immigrants tend to migrate more frequently than natives do.
12
13

14
15 European research on the location decisions of immigrants is scarce. A recent study by
16
17 ASLUND (2005) investigates the initial and subsequent location choices of refugees and
18
19 OECD migrants across municipalities in a natural experimental setting in Sweden. The study
20
21 underlines the main findings of studies from the United States that the presence of co-ethnics
22
23 and a large overall immigrant population has a significant role in determining initial location
24
25 choices and relocation decisions. The study also confirms the role of local economic prospects
26
27 in attracting immigrants. A shift from locations with small populations towards locations with
28
29 large populations is also observed. ASLUND also presents evidence that immigrants' location
30
31 decisions are affected by labour market prospects. Immigrants tend to move from
32
33 municipalities with high unemployment rates to municipalities with lower unemployment
34
35 rates and higher earnings. At the same time, ASLUND also finds that there are concentrations
36
37 of immigrants in municipalities with a relatively large number of welfare recipients; he puts
38
39 no explanation forward for this finding. BOLT and VAN KEMPEN (2003) examined the
40
41 mobility of Surinamese, Turks, and Moroccans from and into poverty neighbourhoods in the
42
43 Netherlands. These authors show that these groups have a greater probability of moving into
44
45 poverty neighbourhoods and a smaller probability of escaping poor neighbourhoods compared
46
47 with native Dutch. They suggest that a combination of a higher income and higher education
48
49 increases the probability of moving out of poverty neighbourhoods. Although a poor
50
51 neighbourhood may not necessarily be ethnically segregated, the opposite is often true:
52
53
54
55
56
57
58
59
60

1
2
3 ethnically segregated areas are often inhabited by people in a relatively poor socioeconomic
4 position (MUSTERD, 2005).
5
6
7

8
9 The residential settlement behaviour of immigrants can be studied with the aid of assimilation
10 theories that describe a process through which immigrants adopt the attitudes and ways of life
11 of the dominant society and obtain a similar socioeconomic position. Spatial assimilation,
12 which is regarded as an ethnic group's geographical proximity to the majority group, is seen
13 as an important stage in this general process. Assimilation is thought to follow social mobility
14 in terms of achievements in education, income, and occupational status (MASSEY &
15 MULLAN, 1984; MASSEY & DANTON, 1985). Residential proximity between an ethnic
16 minority group and the majority group probably enhances a variety of cross-ethnic
17 relationships that are relevant in the achievement of greater social mobility. Spatial
18 assimilation theory has been widely applied to enhance our understanding of the residential
19 patterns of immigrants in North America (SOUTH *et al.*, 2005; FONG & WILKES, 1999).
20 Recent empirical evidence suggests that social mobility does not necessarily lead to spatial
21 assimilation. This appraisal led to a modification of the classical assimilation model, often
22 referred to as *segmented assimilation*. The segmented assimilation perspective suggests that
23 various ethnic groups experience different assimilation patterns given their human and
24 financial capital endowments and proficiency in the dominant local language (SOUTH *et al.*,
25 2005).

45
46
47
48
49

50 *Spatial assimilation*

51
52 Spatial assimilation theory was originally developed to interpret the settlement behaviour of
53 voluntary labour immigrants, mostly from Europe, who arrived in the United States in the
54 early part of nineteenth century. The relevance of this theory is unclear, however, for the
55 behaviour of other types of immigrants: the family and asylum migrants, for example, who
56
57
58
59
60

1
2
3 have comprised a significant part of the immigration flows to Europe since the 1980s. Spatial
4
5 assimilation theory suggests a number of hypotheses that we have tested for new immigrants
6
7 to the Netherlands. First, *new immigrants are expected to settle primarily in neighbourhoods*
8
9 *where co-ethnics are concentrated*. A preference for residing in a neighbourhood inhabited by
10
11 people from the same country of origin could stem from the supply of specific ethnic goods
12
13 and services or from easier access to host-country-specific information through ethnic
14
15 networks. Preferences might also be related to such factors as prejudice, fear of discrimination
16
17 or neighbourhood problems (LOGAN *et al.* 2002). The typical new immigrant is able to utilize
18
19 the help of co-ethnics in obtaining access to housing and labour markets as well as to
20
21 ethnically-specific goods and services.
22
23
24
25

26
27 Spatial assimilation theory also implies that similarities between the Dutch community and
28
29 immigrant groups enhance the residential integration of immigrants within the host country.
30
31 Human capital endowment, proficiency in the local language, and religion are important
32
33 approximates for distance from the host country population. In that sense, immigrants from
34
35 Surinam (a former Dutch colony) are likely to have a closer distance from the native Dutch,
36
37 since they share a similar cultural and religious background and most Surinamers already
38
39 speak Dutch on their arrival. The cultural distance between western immigrants or labour
40
41 migrants and the Dutch can also be seen as relatively small in terms of human capital
42
43 endowment, religious background, and proficiency in English, which is widely spoken in the
44
45 Netherlands. At the other extreme are the immigrants from non-western countries such as
46
47 Turkey, Morocco, Iraq, Somalia, and Iran. They are more likely to be asylum seekers and
48
49 family migrants and may have a greater cultural distance from Dutch society, although in
50
51 various degrees.
52
53
54
55
56

57
58 The second hypothesis concerns the relationship between settlement behaviour and cultural
59
60 distance: the shorter their distance from the native Dutch, the more likely are immigrants to

1
2
3 settle initially and move subsequently into a less segregated neighbourhood. When
4
5 immigrants are categorized by migration motives, we would expect to find a strong effect
6
7 from the presence of co-ethnics on the location choice of new family immigrants. The effect
8
9 could be expected to be smaller for those, such as asylum migrants and students, who had no
10
11 large close ethnic communities in the Netherlands. The effect was expected to be less strong
12
13 for immigrants from western countries, because this group contains labour immigrants and
14
15 their family members.
16
17
18

19
20 Since information on the level of education of immigrants is not included in our data,
21
22 employment status has been used to approximate human capital endowment and the social
23
24 mobility of immigrant groups. Our hypothesis was that employed immigrants move to less
25
26 segregated neighbourhoods and unemployed immigrants move in the opposite direction.
27
28
29

30 Spatial assimilation theory suggests that immigrants initially settle in ethnic enclaves where
31
32 the environmental quality of the neighbourhood is poor. In the Netherlands, regional
33
34 differences in wages are small and the strength of the association between ethnic segregation
35
36 and economic success is doubtful (MUSTERD, 2003). This implies that the local mean wage,
37
38 unemployment and house values are rather more likely to refer to a better quality of housing
39
40 and neighbourhood. Immigrants with more human and financial capital, like labour migrants,
41
42 are hypothesised mainly to choose neighbourhoods where income and house values are high
43
44 and unemployment is low. The location choice of family migrants could also be expected to
45
46 be affected by local labour market conditions, although less so than for labour migrants. Local
47
48 labour market conditions are less likely to affect family migrants directly, but they may be
49
50 effective through the family members who have invited them. The location decisions of
51
52 asylum immigrants were not expected to be sensitive to local labour market conditions
53
54 because they are primarily admitted on the base of humanitarian reasons.
55
56
57
58
59
60

Housing market restrictions

In the Dutch housing market, about half the housing stock consists of rental accommodation, most of which belongs to the social housing sector. The access to social housing is constrained by institutional regulations. Only households with an income below a certain limit are allowed to rent a home in this sector. Additionally, the probability of being eligible for a rental home is directly related to the duration of residence in the municipality. Social housing is concentrated in certain neighbourhoods of large cities and rents in this sector are below market prices. These restrictions induce rationing and lead to a long waiting time for potential renters. This system is clearly unfavourable for those seeking housing from outside the municipality and could influence new immigrants particularly adversely since migrants need to find their first home within a very limited time period with limited information about the local housing market. To capture the effects of housing market restrictions, we used two indicators: the fraction of homeowners in the neighbourhood and the share of the social sector in the municipality. The effect of the share of homeowners was expected to be positive, because it indicates the relative size of the private housing sector, which is not subject to institutional barriers. The effect of the size of the social sector was expected to be negative, because it indicates the extent of the sheltered housing market in the municipality.

The impact of all these variables may vary across immigrant groups. The initial location decisions of new immigrants may be associated with their host country contacts, which may be related to their migration motives. Many immigrants enter the Netherlands on the basis of family reunification or formation, so their residential locations are in fact predetermined: they join existing households. The location choice of family immigrants will not be influenced directly by local housing market restrictions. But, in contrast, the settlement decisions of labour and asylum migrants are likely to be affected by restrictions and opportunities on the local housing market as well as economic factors. Labour migrants, who are often from

1
2
3 western countries, may have been recruited abroad and their initial location is likely to be
4 determined by their job. These people are likely to live close to the company for which they
5 work. So, their location choices are likely to be associated with local economic conditions.
6
7 These immigrants are relatively prosperous and many of them will be able to afford to rent in
8 the private part of the housing market. On the other hand, asylum migrants are *a priori*
9 restricted to the cheap rental housing market. They are obliged to participate in an admission
10 procedure, which takes one to three years. Usually, while they are involved in this procedure,
11 they are obliged to reside at an assigned location and are not registered in the population
12 register: only a small fraction of asylum seekers (about 10 percent) is registered while still in
13 the procedure. After receiving legal status, they register in the population register to be
14 eligible for public services. They are then entirely free to choose their new residential
15 location. Most immigrants from developing countries may be assumed to arrive without any
16 financial assets. While these immigrants have to manage without family support, they are
17 effectively excluded from owner-occupied housing and the more expensive part of the rental
18 sector. They are forced to look for a cheap rental home in a cheap neighbourhood.

39 **DATA AND DESCRIPTIVE STATISTICS**

40
41
42 We used a rich register data file housed at Statistics Netherlands (the Dutch Social-Statistical
43 Database, SSD) and including all legal residents of the Netherlands. Our sample covers all
44 immigrants (foreign-born persons with non-Dutch parents) who arrived in 1999 and were
45 present on the third Friday of September 1999, which is the measurement moment for these
46 data. Subsequently, we followed these individuals for four years: from 1999 to 2003. The data
47 contain longitudinal information about residential locations at neighbourhood level, indicators
48 of socioeconomic and household status, housing conditions, and some neighbourhood
49 characteristics. Although the literature emphasises the key role of education in explaining
50
51
52
53
54
55
56
57
58
59
60

1
2
3 location decisions, unfortunately the impact of education on immigrants' settlement behaviour
4 could not be explored in this study.
5
6
7

8 We used the neighbourhood as the geographical unit of analysis. This is the smallest unit
9 defined in the data, with on average about 1900 residents in 1999, given the total population
10 was about 15.7 million and the number of neighbourhoods suitable for analysis was 8275.
11 This strategy provides several advantages. First, such a small size of spatial unit enabled us to
12 account for the great variation of shares of ethnic minority populations in the neighbourhoods
13 of larger cities. Second, neighbourhoods are in fact small spatial areas where interactions
14 between people of different origin are likely to occur. Third, using the smallest areas provides
15 maximum flexibility to cluster these areas on the basis of our own criteria, in our case degrees
16 of ethnic concentration.

30 Table 1 gives the mean values of the variables by country of birth for immigrants from six
31 selected countries, one year after the immigrants' official settlement in the Netherlands. The
32 data we used range from 1999 through 2003, so we selected the year 2000. We chose it,
33 because the labour market position of immigrants is more representative one year after arrival,
34 while their geographical distribution is close to that on arrival¹. More than 1100 of these
35 immigrants entered the Netherlands in 1999. They were Afghanis, Chinese, Iraqi, Surinamese,
36 Turks, and Moroccans. In the Netherlands, Surinamese, Turks and Moroccans comprise the
37 largest communities. New immigrants from these countries usually come to the Netherlands
38 on the basis of family ties. Immigrants from Afghanistan and Iraq mainly enter as asylum
39 seekers; there is no large community of Iraqis or Afghanis in the Netherlands. The Chinese
40 take an intermediate position; new Chinese immigrants were allowed to enter for a variety of
41 reasons in 1999. Non-western immigrants are a highly heterogeneous category, comprising
42 immigrants entering the Netherlands for a variety of migration motives. The rest of the
43 immigrants are clustered into two categories: other non-western and western.
44
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 Alternatively, for the analyses of initial location choices, immigrants are categorised by
4 migration motives as assessed by the Immigration and Naturalisation Service (IND) at entry.
5
6 Four main migration motives are distinguished: labour, asylum, family reunification, and
7
8 family formation. Although the migration motive may include some measurement errorⁱⁱ, this
9
10 variable was expected to play an important part in explaining the location decision. Table 1
11
12 indicates a strong association between country of birth and migration motive. There are
13
14 substantial differences in the individual and household characteristics as well as in the spatial
15
16 distribution of immigrants by country of birth. Turkish, Moroccan, and Surinamese
17
18 immigrants are usually family migrants. Asylum migrants come mainly from Afghanistan,
19
20 Iraq, and other non-western countries. Labour migrants are predominantly from western
21
22 countries. Immigrants from non-western countries tend to be younger, renters rather than
23
24 homeowners, more frequently unemployed, and residing in locations where unemployment is
25
26 relatively high and wages and house values are low. Immigrants from Afghanistan and Iraq,
27
28 who are usually asylum migrants, are more often young males. They are often unemployed
29
30 and live in a single-person household, while immigrants from Turkey, Morocco, and Surinam
31
32 more frequently live in a couple household.
33
34
35
36
37
38
39
40

41 Immigrants predominantly settle in large cities. Table 1 shows that almost 59 percent of
42
43 Surinamese and 51 percent of Moroccans were located in the four largest cities one year after
44
45 arrival, with a clear preference for Amsterdam. Among the immigrants from the classic
46
47 countries of origin in Dutch immigration history, the Turks are relatively more diffused.
48
49 Immigrants from Iraq and Afghanistan who entered the country as asylum seekers and who do
50
51 not have a large community of co-ethnics in the Netherlands are scattered over the country.
52
53 This dispersion is probably the result of the proactive government refugee settlement policies
54
55 applied during the period between the asylum application and admission, after which refugees
56
57 are free to move. Chinese immigrants, for whom there is no single particularly dominant
58
59
60

1
2
3 motive, are located mostly in Rotterdam. The settlement pattern of immigrants from other
4
5 non-western and western countries appears to be similar to that of the Chinese.
6
7

8
9 It is worth noting that not all the immigrants who arrived in 1999 stayed in the Netherlands
10
11 during the whole period. The last row of table 1 gives the percentages of immigrants who
12
13 were no longer present in 2003. Western, other non-western, and Chinese immigrants are
14
15 particularly less likely to stay: of these, 33, 21, and 16 percent respectively left the
16
17 Netherlands within 4 years. Those who left are generally labour migrants, especially those in
18
19 the Western category. Among the leavers, there might also be some asylum migrants who had
20
21 a temporary residence permit that was annulled after the country of origin had been declared
22
23 to be a safe country.
24
25
26

33

34 35 **DETERMINANTS OF INITIAL LOCATION CHOICES**

36
37 Because we do not have any information about the socioeconomic background of immigrants
38
39 prior to immigration, we have focused on the characteristics of neighbourhoods and used a
40
41 simple linear regression model to study the determinants of the settlement behaviour of
42
43 immigrants groups distinguished by country of birth and, alternatively, by migration motive.
44
45 The unit of analysis is the neighbourhood, so there is no opportunity to control for the
46
47 individual characteristics of the migrants. In the analysis of further moves, we were able to
48
49 perform a limited number of controls: we could control for gender, age, housing tenure,
50
51 household composition, and employment status. No information about level of education was
52
53 available, however.
54
55
56
57

58
59 The number of immigrants settling in a neighbourhood is regressed on the demographic and
60
socioeconomic characteristics of neighbourhoods and municipalities:

$$I_i = \alpha + N_i\beta + M_i\delta + \varepsilon_i \quad (1)$$

where I_i is the number of immigrants in neighbourhood i who entered the Netherlands in 1999. N_i is a vector of neighbourhood characteristics that include the shares of the largest ethnic minority groups (Moroccan, Turkish, Surinamese/Antilleans, other non-western and western), the fraction of owner occupied homes, the share of social housing, the size of neighbourhood population, and the logarithm of the average wages for earned income.

M_i is a vector of municipality characteristics covering local labour market conditions in terms of fractions of the medium- and highly-skilled labour force, as well as the unemployment rate.

Additionally, the mean value of all homes in the municipality (rented and owner-occupied) is included to control for housing market conditions and the size of the municipal population to capture large municipality effects. We have also used fixed effects for the four largest cities.

Equation 1 was estimated for the seven separate immigrant groups by country of birth. Additionally, separate models were estimated for labour and asylum migrants, and for family migrants from Turkey, Morocco, and Surinam. Because neighbourhoods are nested in municipalities, we relaxed the assumption of the independent observation of the neighbourhoods by correcting for a possible correlation of standard errors for neighbourhoods within a municipality. The estimation results are reported in Tables 2 and 3. In addition to the coefficients, the standardised (beta) coefficients are also presented to show the relative strength of the covariates used. Immigrants' initial settlement patterns seem to be strongly associated with neighbourhood prosperity in terms of logarithmic mean value of houses, as proposed by spatial assimilation theory. There is an inverse relationship between the number of immigrants entering a neighbourhood and house values. This relationship is particularly strong for almost all immigrant groups from non-western countries. The inverse effect of neighbourhood prosperity is smallest for Surinamese and western immigrants. The results

1
2
3 unambiguously confirm the findings from the international literature that immigrants' location
4 choices are largely determined by the fraction of the neighbourhood population made up by
5 ethnic minorities from the same origin. This association is the strongest for immigrants from
6 Morocco, who have large communities of co-ethnics in the Netherlands. A one standard
7 deviation increase in the fraction of Moroccans in the neighbourhood leads to a 0.39 standard
8 deviation increase in the predicted number of Moroccan immigrants settling in the
9 neighbourhood. The association between the residential location of Turkish immigrants and
10 their co-ethnics is remarkably weaker than for Moroccan immigrants. This association is
11 comparable with the association for western immigrants. A one standard deviation increase in
12 the share of Turkish and western people results in a 0.24 and 0.17 standard deviation increase
13 in the number of immigrants from the same country of origin. The location choices of
14 immigrants from China, Iraq, and Afghanistan are associated positively with the share of non-
15 western ethnic minorities, but this association is less pronounced than for the other groups
16 mentioned. No association was found for the residential location of Surinamese immigrants
17 and their co-ethnics. This outcome is closely related to the estimation procedure: when the
18 independent observation of neighbourhoods is assumed, a strong association is found for the
19 Surinamese. The association is the strongest for them of all the groups, despite the nested
20 nature of neighbourhoods within the municipality. This association is probably related to the
21 strong concentration of Surinamese in Rotterdam and Amsterdam.

The relative size of a particular ethnic group in a neighbourhood is associated with the
destination location of groups other than immigrant co-ethnics in various ways. The number
of Turkish immigrants is positively related to the concentration of Moroccans in the
neighbourhood in addition to the association with the presence of co-ethnics. Moroccan
immigrants settle more frequently in the neighbourhoods where Surinamese are concentrated,
and notably not in the neighbourhoods where Turks are clustered. This is a remarkable

1
2
3 outcome, because there are religious and socioeconomic similarities between Turks and

60
outcome, because there are religious and socioeconomic similarities between Turks and
Moroccans, while Surinamese differ from these groups in their religious and linguistic
background as well as in their migration history (Zorlu & Hartog, 2002). Our prediction for
Surinamese immigrants in that sense is confirmed: the initial location of Surinamese
immigrants is not associated with the concentration of Turks and Moroccans. There is an
adverse relationship between the number of immigrants from western countries entering a
neighbourhood and the concentration of Surinamese/Antilleans, Turks and Moroccans.
Conversely, Turkish, Moroccan, and Surinamese immigrants are less likely to settle in
neighbourhoods where western immigrants are concentrated. This pattern emphasises the
strong effect of ethnic ties and socioeconomic dissimilarities between western and non-
western immigrants, given all other restrictions and housing market rigidities that seriously
constrain a free choice of residential location.

The results also indicate that the initial location of immigrants from the Turkish and
Moroccan groups is more often a neighbourhood where the proportion of people living in an
owner-occupied home is relatively high. A greater number of Afghan immigrants is positively
associated with the prosperity of the neighbourhood as measured by the average wage level
for earners. This relationship seems remarkable considering their socioeconomic position but
understandable because an overwhelmingly large share of them entered the Netherlands as
asylum migrants who were subject to government settlement policies, rather than being able
to make their own location choices. Alternative models estimated for these groups indicate
that the number of Turkish and Moroccan immigrants is negatively associated with the
income level in the neighbourhood when the effects for the ethnic composition of
neighbourhoods are not controlled (not shown here). This result implies that there is a positive
association between the settlement behaviour and the neighbourhood prosperity, even for
Turkish family migrants, given the ethnic composition of the neighbourhood. As a matter of

1
2
3 course, the effect of the neighbourhood population variable is positive and highly significant
4
5 for all the groups. Another interesting finding is the strong inverse relationship between the
6
7 mean value of the homes in a neighbourhood and the number of immigrants from any origin.
8
9

10 Immigrants evidently tend to locate initially in neighbourhoods with cheap housing stock.
11

12
13 The lower panel of table 2 reports the effect of the variables on the municipality level.
14

15 Turkish, Moroccan, and Afghan immigrants are more likely to settle in municipalities with
16
17 low unemployment levels, which suggests their sensitivity to local economic conditions. The
18
19 settlement behaviour of other groups seems to be insensitive to economic indicators.
20

21
22 Furthermore, Moroccan, Chinese, and western immigrants settle more frequently in
23
24 municipalities where a relatively large share of the labour force is highly skilled. Because
25
26 Moroccan and Chinese immigrants are on the whole less skilled than the native Dutch, this
27
28 marked association probably indicates that Moroccan and Chinese immigrants look for job
29
30 opportunities complementary to the highly-skilled labour force in the local labour market. The
31
32 more highly-skilled western immigrants may search for jobs requiring high skills, in
33
34 competition with the highly-skilled among the native Dutch. As expected, the controls for the
35
36 largest Dutch cities are often highly significant. However, the effects vary across the groups.
37
38
39

40
41 Turkish and Moroccan immigrants and western migrants seem to be concentrated in
42
43 Amsterdam, Rotterdam, and The Hague, while the Surinamese are only concentrated in
44
45 Amsterdam and Rotterdam. Only western immigrants are more often found in Utrecht. The
46
47 other groups are diffused over the country.
48
49

50
51 The determinants of initial locations were also investigated for separate migration motives to
52
53 obtain a more detailed picture of settlement patterns. To retain large enough numbers of
54
55 observed migrants to estimate the models by motive, we had to sacrifice considerable detail
56
57 with regard to country of origin. Labour migration and asylum migration were analysed for all
58
59 countries of origin together. Because those migrating for family reunification or family
60

74

1
2
3 formation came mainly from Turkey, Morocco, and Surinam and there were enough family
4 migrants from each of these countries, we could estimate separate models for family-related
5 motives for these three countries. Table 3 reports the results. Labour migrants, frequently
6 coming from western countries, choose those neighbourhoods with higher levels of earnings
7 and higher concentrations of ethnic minority groups from western and other non-western
8 countries. The settlement pattern of asylum migrants is strongly influenced by the share of
9 other non-western immigrants but negatively influenced by the share of Surinamese. The
10 location decision of asylum migrants is apparently not influenced by good economic
11 prospects: asylum migrants are more frequently located in municipalities with higher
12 unemployment rates.
13
14

16
17
18
19
20
21
22
23
24
25
26

27 Estimations for family migrants are specified for the two separate motives of family
28 migration: family reunification and family formation. This is because these two groups are
29 expected to differ in their age and skill distributions and in their dependence on fellow
30 migrants. Those migrating for family reunification are generally younger and possibly more
31 dependent on their family, while those migrating for family formation are usually young
32 adults. Interestingly, the settlement patterns of Turkish and Moroccan family migrants show
33 strong similarities: those who entered the Netherlands on the basis of family reunification
34 seem to be slightly less sensitive to both the presence of co-ethnics and the economic
35 indicators of the residential location (mean wage and unemployment rate). This outcome does
36 not conform to the expectation that immigrants with a family reunification motive settle more
37 frequently in neighbourhoods where their co-ethnics are concentrated. This finding might be
38 the case for immigrants entering on the basis of family reunification to join a family that has
39 moved to a less segregated neighbourhood after improving the household's economic
40 position. Among Surinamese immigrants, no differences were observed across the types of
41 family migration.

3 Additionally, we estimated all models including expenditures and taxes of municipalities,
4 which were supposed to measure the economic attractiveness of the municipality. These
5 variables did not improve the models, in contrast with what some American research suggests
6 (BORJAS, 1999). The much smaller differences between residential areas in the Netherlands
7 than between those in the United States could explain the modest role of these factors here.
8
9
10
11
12
13
14

15 16 *Robustness of Estimations*

17
18 Because some neighbourhoods attract no immigrants and the number of immigrants clustered
19 into groups is sometimes smaller than the number of neighbourhoods, we estimated
20 regression equations for the sub-samples, covering only neighbourhoods to which immigrants
21 from the relevant group had immigrated, to check whether a heteroscedasticity problem had
22 occurred. This procedure generated larger coefficients for the covariates of neighbourhood
23 ethnic composition and some other covariates with higher significance levels, as we expected.
24 However, this approach ignores those neighbourhoods without any members of the relevant
25 group as an option that an immigrant could choose. Consequently, this approach generates an
26 overestimation of a neighbourhood's ethnic composition and other covariates. We therefore
27 preferred estimations that included all neighbourhoods, but at the same time we corrected for
28 a possible heteroscedasticity problem and presented corresponding robust standard errors.

43
44

45 Another important issue is that the separate estimations of equation 1 for immigrant groups
46 implicitly assume that the error terms of the separate regressions are uncorrelated, which
47 might not be the case. We therefore also estimated the set of multiple regression equations for
48 the immigrant groups simultaneously, allowing for correlation among the error terms of the
49 multiple equation system. This method generated results that were very similar to those of the
50 separate estimations presented and discussed above.

<<TABLE 2>>

<<TABLE 3>>

SUBSEQUENT GEOGRAPHICAL MOBILITY

Descriptive results

Table 4 reveals a substantial geographical mobility among immigrants in the first years after their entrance in 1999 up to 2003. The share of movers, and particularly the share of movers between municipalities, is remarkably large compared with the total population of the Netherlands. About 8 percent of the total population moves annually, with two thirds remaining in the same municipality. Non-western immigrants move more frequently than western immigrants: about 20 percent versus about 15 percent annually. Chinese, Surinamese, and Iraqis changed their residential location particularly frequently. The frequency of moves generally shows a rising trend in the first two years. It is also interesting to note that Turkish, Moroccan, and Surinamese immigrants move more often within the same municipality, whereas Iraqis and Chinese tend to move between municipalities. When immigrants are distinguished by migration motive, asylum migrants are found to be the most frequent movers; they move relatively more often between municipalities.

<<TABLE 4>>

To investigate the dynamics of ethnic segregation, we constructed three types of neighbourhood: *native*, *mixed*, and *segregated*. A classification into separate types was necessary, because we wished to estimate the transition probabilities between separate neighbourhood types. The distinction between the types is based on the level of ethnic

concentration in the neighbourhood. The fraction of ethnic minorities from non-western countries in the population of the Netherlands is about 10 percent, so this percentage was used as the demarcation line between *native* and *mixed* neighbourhoods. *Segregated* neighbourhoods are those in which non-western ethnic minorities make up at least 35 percent of the neighbourhood population. This definition follows the criterion of 4 standard deviations used by MUSTERD and DE VOS (2005). *Mixed* neighbourhoods are those with an ethnic minority population of between 10 and 35 percent.

Since we were interested in the dynamics of segregation, we tracked the relocation behaviour of individuals living in a certain type of neighbourhood to the other two neighbourhood types and the same type. Considering movers only, the probabilities of moving from one type of neighbourhood to another type are given by a 3x3-dimensional matrix (\mathbf{P}). Each row represents the probabilities of ending up in each of the three destination-neighbourhood types when moving from an origin neighbourhood type. Thus, the rows of this matrix each add up to one. The matrix is formally given as

$$\mathbf{P} = \begin{bmatrix} p_{NN} & p_{NM} & p_{NS} \\ p_{MN} & p_{MM} & p_{MS} \\ p_{SN} & p_{SM} & p_{SS} \end{bmatrix}, \quad \text{with } \sum_{i,j=1}^3 p_{ij} = 1 \quad (2)$$

where the subscripts attached to the probabilities (N, M, S) refer to the neighbourhood segregation types native, mixed, and segregated and the probability of being in any particular state, p_{ij} at time $t+1$ depends on the state at the previous time, t , given as $P(p_{ij(t+1)} | p_{ij(t)})$.

Table 5 shows the origin-destination matrix for mover person-year within the period 1999 to 2003 by country of birth and migration motive. The propensity to move from *native* and *mixed* neighbourhoods to *segregated* neighbourhoods is the highest for Surinamese and Moroccans. Immigrants from non-western countries who reside in *segregated* neighbourhoods are more likely to move to another dwelling within the same neighbourhood

1
2
3 type. This pattern is particularly strong for Turkish, Moroccan, and Surinamese immigrants,
4
5 for whom the probabilities of moving to a *native* neighbourhood are very small. When
6
7 migration motives are considered, a relatively high probability of moving from *native* to
8
9 *segregated* neighbourhoods is observed for asylum migrants and students. The relatively
10
11 greater mobility from segregated to less segregated neighbourhoods for Iraqis than for
12
13 Afghans is striking, but remains hard to explain with the information available on the
14
15 similarity of their backgrounds (HARTOG & ZORLU, 2005). Family migrants residing in
16
17 *segregated* neighbourhoods are less likely to move to *native* neighbourhoods.
18
19
20
21

22
23 <<TABLE 5>>
24
25
26
27
28
29
30
31

32 Table 6 decomposes movers into those moving within and between municipalities. The
33
34 propensity to move within the same neighbourhood type is particularly strong when
35
36 immigrants move within a municipality: the shares are around 60 and 70 percent for native
37
38 and segregated neighbourhoods respectively. The probability of moving between native and
39
40 segregated neighbourhoods is very small, although immigrants are more likely to move to
41
42 more segregated areas than from segregated to native neighbourhoods. When movers between
43
44 municipalities are considered, movers are more likely to move to other neighbourhood types:
45
46 There is a greater mobility from less to more segregated neighbourhoods and particularly in
47
48 the opposite direction: that is, from segregated neighbourhoods to mixed and native
49
50 neighbourhoods.
51
52
53
54
55
56
57
58
59
60

<<TABLE 6>>

The mobility patterns of new immigrants cannot be fully described by considering movers alone. The distribution of non-movers over a neighbourhood is also an important factor. Table 7 gives the initial distribution of immigrants upon arrival and the net changes in the relative share of immigrants in the different neighbourhood types. It is evident that the relative share of immigrants living in native neighbourhoods declines for all immigrant groups, while the relative shares of mixed and segregated neighbourhood increase for almost all groups, except the Chinese and Surinamese. The decline in the share of immigrants living in native neighbourhoods is the strongest for Afghans, followed by Iraqi and other non-western immigrants. Furthermore, the decrease in the share of Chinese living in mixed neighbourhoods is remarkable, as is the decrease in the relative share of Surinamese as a single group in segregated neighbourhoods.

<<TABLE 7>>

The Model

We assume that, in the years following arrival, an immigrant has a variety of location options available from which to choose, regarding the initial location as the starting point. Staying in the original location is also an option.

Consider the time periods elapsed since the immigrant arrived. Each period is a discrete time interval of 1 year with the measurement moment in September. The location choices of immigrants are first observed for September 1999 and subsequently for each year up to 2003.

Corresponding with these time periods, the vector of location choices of an individual i is given by

$$(k_{i0}, k_{i1}, k_{i2}, k_{i3}, k_{i4}) \quad (3)$$

where k_{ij} is the location chosen by individual i at time j . The probability of being observed in k_1 in time period 1 is conditional on the first location, $\Pr(k_1|k_0)$. This implies that individuals living in a particular neighbourhood type evaluate the expected utility of their moving elsewhere on the basis of information gathered for the place. Considering the three types of neighbourhood distinguished as the possible choices, the probability that an individual is observed in k_2 in period 2 is the sum of the probabilities that the individual moves to any of the 3 alternatives in period 1 multiplied by the probability that the individual moves from this location to k_2 in period 2. Correspondingly, the probabilities in periods 3 and 4 are conditional on the preceding periods. The probability that the individual is observed in k_4 in the last period, period 4 is

$$\Pr(k_4|k_0) = \sum_{k_3=1}^3 \Pr(k_4|k_3) \sum_{k_2=1}^3 \Pr(k_3|k_2) \sum_{k_1=1}^3 \Pr(k_2|k_1) \Pr(k_1|k_0) \quad (4)$$

The neighbourhood types are assumed to be independent and unordered alternative locations. While this assumption may not be totally realistic for each individual migrant, it has the great advantage of enabling the probability of ending up in a certain location to be modelled using a multinomial logistic regression model. Let us define the probability of being observed in each destination neighbourhood p_{ijt} in time t based on the neighbourhood type of origin j and characteristics of immigrants in time $t-1$ as follows:

$$\ln(p_{ijt}/p_{i0t}) = \phi + X_{i(t-1)}\lambda + N_{i(t-1)}\eta + \nu \quad (5)$$

where p_{ijt}/p_{i0t} is the odds that the individual i is observed in the j th neighbourhood category at time t relative to not moving (staying in the origin neighbourhood type $_0$) at time t . A vector of the characteristics of individuals and the locations where individuals lived at time $t-1$ is given by $X_{i(t-1)}$ and $N_{i(t-1)}$. Since individuals are likely to base their decisions on the information

available at time $t-1$, all covariates are lagged by one year, which also helps to avoid endogeneity bias.

Since we are interested in the individual determinants of moves from and to more segregated neighbourhoods, multinomial logistic regression models have been used to estimate the individual determinants of transition probabilities of moving from an origin neighbourhood to another neighbourhood. An individual i 's contribution to the likelihood function in the individual's residential location j at the end of year $t-1$ is given by the standard form of the multinomial logit model:

$$P_{ijt} = \exp(X_{i(t-1)}\lambda_j + N_{i(t-1)}\eta_j) / \sum_{k=1}^3 \exp(X_{i(t-1)}\lambda_k + N_{i(t-1)}\eta_k) \quad (6)$$

The estimation strategy is as follows. First, immigrants are observed in the separate neighbourhood types of native, mixed, and segregated in period $t-1$. Subsequently, for each of these sub-samples, the transition probabilities relative to staying in the origin category are estimated separately by a standard multinomial logistic regression procedure. Our dependent variable has four response categories: *native*, *mixed*, *segregated*, and *staying*, which is the reference category. Although equation 3 suggests that the probability of being observed in a neighbourhood type in time t is correlated with the location in time $t-1$, we have ignored these correlations, because these transition probabilities are hard to construct and to estimate for more than two response categories.

We simply estimated the probabilities of being observed in each destination neighbourhood type based on the neighbourhood type of origin, using the pooled data for 1999-2003. To assess whether this simplification was justified, we also estimated the probabilities separately for each year of observation. This procedure generated very similar results. Since individuals contribute to the analysis up to four times, the standard assumption of the stochastic independence of error terms is violated. The models were therefore estimated with corrections

1
2
3 for multiple observations for an individual to ensure that standard errors were not biased.
4
5 Furthermore, we are aware that parents usually make location decisions and children have no
6
7 direct influence on them. Estimations are therefore restricted to the population aged 18 years
8
9 and older, because no identifier for the household is included in the data. We believe that
10
11 sufficient account is taken of the absence of a household identifier by using controls for
12
13 household type together with age in a flexible functional form.
14
15

16 17 18 *Model results* 19

20
21 The results for the three sub-samples are reported as relative risk ratios in table 8. The most
22
23 important result is the clear pattern of concentration into more segregated neighbourhoods
24
25 among immigrants from non-western countries, given all the individual and neighbourhood
26
27 characteristics in the models. Those who settled initially in a less segregated neighbourhood
28
29 tend to move towards more segregated neighbourhoods in the four consecutive years, which
30
31 confirms the findings of ASLUND (2005). This pattern is particularly strong for asylum
32
33 migrants, who move the most frequently of all the immigrant groups. Asylum migrants are
34
35 followed in intensity of mobility by Surinamese, Moroccan, and Turkish immigrants, who
36
37 also tend to move into more segregated neighbourhoods. Bearing in mind that asylum
38
39 migrants are initially much more diffused over the country, while immigrants from Turkey,
40
41 Morocco, and Surinam are initially already concentrated in more segregated neighbourhoods,
42
43 it would therefore seem that asylum migrants 'catch up' with other non-western immigrants in
44
45 terms of concentration. It is remarkable that the concentration of Surinamese, Moroccan, and
46
47 Turkish immigrants continues in the first few years after arrival, although the tendency does
48
49 not necessarily persist over a longer period. Evidence from traditional immigration countries
50
51 indicates a turn after the initial tendency of moving into more segregated areas
52
53 (FUNKHOUSER, 2000).
54
55
56
57
58
59
60

1
2
3 As reported above, asylum migrants move most frequently irrespective of the neighbourhood
4 type in which they reside and their destination neighbourhood type is more likely a more
5 segregated neighbourhood. When the residential location of asylum migrants upon arrival is
6 in a *native* neighbourhood, they are about 1.5 times more likely to move within the same
7 neighbourhood type as are labour migrants (the reference category), and respectively 2.9 and
8 almost 8.3 times more likely to move into a mixed or a segregated neighbourhood type. If
9 they have already settled in a mixed neighbourhood, they are almost 1.4 times more likely to
10 move a neighbourhood type that is not more segregated than their initial neighbourhood.
11 However, they have a 3.2 times higher probability of moving into a segregated neighbourhood.
12 If immigrants who entered the Netherlands on the basis of family formation or family
13 reunification settled initially in a native or mixed neighbourhood, they have a higher
14 probability of moving into neighbourhoods with a higher degree of ethnic segregation. Those
15 who settled in a segregated neighbourhood are the most likely to remain in the same
16 neighbourhood. Those forming family are in that case less likely to move to native
17 neighbourhoods.

18
19
20
21

23
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39 Surinamese, Moroccan, and Turkish immigrants living in a native neighbourhood are
40 respectively about 1.9, 1.9, and 2.1 times more likely to move to mixed neighbourhoods, and
41 2.9, 3.8, and 3.3 times more likely to move to segregated neighbourhoods than are western
42 immigrants (the reference group). If Surinamese, Moroccan, and Turkish immigrants live in a
43 mixed neighbourhood, they are 5.8, 3.5 and 3 times more likely to move to a segregated
44 neighbourhood than are western immigrants, while the relative probabilities of moving into a
45 native neighbourhood for Moroccan and Turkish immigrants are about 0.5 and 0.6. When
46 these immigrants have already settled in a segregated neighbourhood, they are more likely to
47 stay in the segregated neighbourhood. If they move, they do so more often to another
48 segregated neighbourhood. A similar pattern holds for immigrant groups from other non-
49
50
51

3 western countries such as Iraq, Afghanistan, and China, but for them the effects are less
4
5 strong.
6
7

8
9 The estimated differences in the residential mobility patterns of immigrant groups confirm
10
11 some predictions of spatial assimilation theory. The probabilities of moving into a more
12
13 segregated neighbourhood are relatively low for immigrants from western countries; these
14
15 people are supposed to be at a shorter distance from the native Dutch. The probabilities of
16
17 moving from native into more segregated neighbourhoods are also lower for Surinamese
18
19 immigrants than for non-western immigrants, while the converse holds for Surinamese
20
21 residing in mixed and segregated neighbourhoods. Strikingly, neither group has a smaller
22
23 probability of moving into less segregated neighbourhoods, while Turkish and Moroccan
24
25 immigrants have a stronger tendency to move towards more segregated neighbourhoods: the
26
27 probabilities of moving into a more segregated neighbourhood are significantly greater and
28
29 the probabilities of moving into a less segregated neighbourhood are smaller.
30
31
32
33

34
35 One may ask whether the ethnic composition of the initial neighbourhood where an
36
37 immigrant settled upon arrival has any effect on the subsequent mobility pattern. The relative
38
39 risk ratios for the variables capturing neighbourhood ethnic composition in 1999 show that
40
41 the ethnic composition of the initial neighbourhood has a modest effect. A higher
42
43 concentration of Surinamese in the initial neighbourhood is associated with a smaller
44
45 probability of moving into a less segregated neighbourhood, while a higher concentration of
46
47 other non-western immigrants is positively associated with a slightly higher probability of
48
49 moving into more segregated neighbourhoods.
50
51
52

53
54 The estimates also account for individual and neighbourhood characteristics. First, age and
55
56 gender do not seem to play a prominent part in explaining the mobility of immigrants. There
57
58 is some indication that older immigrants are less likely to move. These small effects are
59
60 possibly the result of less variation in the age structure of immigrants: 31.9 on average in

1
2
3 2000 for the population aged 18 years and older. The inhabitants of a rented dwelling are
4 more likely to move to a more segregated neighbourhood. If renters live in a segregated
5 neighbourhood, they are most unlikely to move. One-person households and couples without
6 children are more likely to move, while couples with children are relatively less likely to
7 move than households without children, which is in line with the internal migration literature.
8 If couples with or without children move, they are more likely to choose a less segregated
9 neighbourhood, and so are one-person households.

10
11
12
13
14
15
16
17
18
19
20 Immigrants in paid employment move more frequently and their destination is more likely to
21 be a less segregated neighbourhood. Unemployed immigrants, in contrast, are likely to move
22 into more segregated neighbourhoods. This outcome suggests that a weak labour market
23 attachment usually accompanied by a poor socioeconomic position is associated with a higher
24 probability of moving to a more segregated neighbourhood. Conversely, a stronger labour
25 market attachment in terms of a job and associated with a greater accumulation of human and
26 financial capital enables an individual to choose where to move more freely. These results
27 clearly support the prediction of spatial assimilation theory, that social mobility can generate
28 spatial mobility towards areas with a greater share of the dominant group.
29
30
31
32
33
34
35
36
37
38
39
40
41

42 To capture composition effects with regard to unemployment, two unemployment variables
43 have been constructed: one for the entire labour force and one exclusively for the native
44 Dutch labour force in the neighbourhood. Since these two variables are used in the models
45 simultaneously, the coefficient for the first gives the effect of unemployment among the non-
46 native labour force on the probability of moving. In fact, the effects of these two variables are
47 significantly different for residents of the three neighbourhood types. Greater unemployment
48 among ethnic minorities is consistently positively associated with a greater probability of
49 moving into a more segregated neighbourhood, while the converse holds for unemployment
50 among the native Dutch labour force. Higher mean earnings in the neighbourhood do not
51
52
53
54
55
56
57
58
59
60

1
2
3 generate a greater probability of moving to a less segregated neighbourhood. Higher earnings
4 is associated with a lower probability of moving. A similar effect is observed for mean value
5
6 of houses in the neighbourhood. House values in the neighbourhood seem to have a small
7
8 negative effect on the probability of move, particularly in less segregated areas.
9
10

11
12 A neighbourhood is small in size and can hardly be seen as an independent local labour
13 market. Unemployment and lower earnings in a neighbourhood therefore probably indicate a
14 concentration of poor people rather than an unfavourable local labour market. In the Dutch
15 context, municipalities can be seen more convincingly as local labour markets. Hence,
16 unemployment in the municipality is also included in the models. A higher unemployment
17 rate in the municipality is associated with a higher probability of moving to a more segregated
18 neighbourhood for those who reside in a *native* neighbourhood. In addition to unemployment,
19 we also controlled for the relative size of the medium- and highly-skilled labour force in the
20 municipality, considering the share of low skilled as reference. An immigrant residing in a
21 segregated neighbourhood associated with a higher share of the medium and highly skilled
22 labour force carries a lower probability of moving in any direction. When the neighbourhood
23 type is native with a higher share of medium skilled labour force, an immigrant has a lower
24 probability of moving to more segregated neighbourhoods. Living in a municipality with a
25 greater share of social housing seems to be associated with a greater probability of moving
26 into a more segregated neighbourhood, but this effect is very small.

47
48

49 Finally, it is worth noting that the shift from less segregated to *segregated* neighbourhoods is
50 very strong for immigrants living in The Hague, Rotterdam, Utrecht, and Amsterdam. This
51 finding is in fact not surprising, since there are relatively many segregated neighbourhoods in
52 the four largest cities.

<<TABLE 8>>

Robustness of the results

To ensure the robustness of our results on residential relocations, we conducted some checks. First, we estimated models including unambiguously exogenous variables only, such as gender, age, ethnic origin, and migration motive. These restricted models provided more pronounced estimates for age and gender, but the general pattern of mobility towards more segregated neighbourhoods remained much the same. We also repeated all estimations for the separate populations of Turkish, Moroccan, and Surinamese immigrants. The results confirmed the mobility patterns found for these groups.

The pooled estimations impose, in effect, a uniform structure on the likelihood functions over the periods considered. This strategy may not be appropriate if in every subsequent year different factors are at work in determining location choices. Therefore, we alternatively estimated the transition probabilities for each separate year (2000-2003) given the location at time $t-1$. The main results remained completely intact. An additional finding was that the probability of moving to a *segregated* neighbourhood among immigrant groups from non-western countries increased during the first three years from arrival, after which the probability stagnated. It is also striking that single-person households and couples without children tended to move to *segregated* neighbourhoods in the second year following arrival (the year 2000), regardless of the segregation level of their neighbourhood of origin. Moreover, an overwhelmingly large share of the moves among the inhabitants of the largest cities from *native* and *segregated* neighbourhoods occurred in the third and fifth years (2002 and 2003).

1
2
3 Finally, we also estimated models for the first move only. These estimations provided results
4 similar to those presented. This check ensures that the results are not biased by the presence
5 of multiple movers (*chronic movers*; compare MORRISON, 1971).

10 11 CONCLUSIONS

12
13
14 The rise of ethnic concentrations in large European cities and the social problems associated
15 with these concentrations require a better understanding of the mechanisms underlying ethnic
16 residential segregation. This study provides empirical evidence on one important channel of
17 segregation dynamics: the contribution of new immigrants to ethnic residential segregation in
18 the Netherlands. The implications of the findings from this study are possibly also applicable
19 to other European countries attracting a substantial number of immigrants.
20
21
22
23
24
25
26
27
28

29 Using a unique longitudinal database, this study examined the initial location settlement
30 patterns, and subsequent relocations of the entire immigrant population arriving in the
31 Netherlands in 1999. The study accounted for individual demographic and socioeconomic
32 characteristics and neighbourhood characteristics as well as typical restrictions on the Dutch
33 housing market. The evidence suggests that there is a substantial mobility of immigrants in
34 the first years following arrival, particularly among immigrants from non-western countries.
35
36 Non-western immigrants not only settle initially in more ethnically segregated
37 neighbourhoods, but also tend to migrate to segregated neighbourhoods. The propensity to
38 remigrate towards more segregated neighbourhoods is particularly strong in the four largest
39 cities: The Hague, Rotterdam, Utrecht, and Amsterdam. This high mobility leads to a decline
40 in the share of immigrants residing in native neighbourhoods within the first five years after
41 immigration. The analysis has shown that initial location choice only explains a part of
42 immigrant concentration

3 The results also demonstrated distinct settlement trajectories for asylum migrants, other non-
4 western migrants, and western immigrants in initial and subsequent settlement patterns. The
5 settlement and mobility patterns of asylum migrants are markedly different from those of
6 other migrants. They are initially much more diffused over the country, probably as a result of
7 specific government settlement policies, and their settlement pattern is not sensitive to local
8 economic conditions. However, in the course of time, asylum migrants show the strongest
9 tendency of all migrant groups to move to more ethnically segregated neighbourhoods. This
10 particularly strong tendency implies that government settlement policies designed to regulate
11 only initial settlement locations have a limited impact and can hardly realise a diffusion of
12 immigrants over the country.

25
26

27 Considering other non-refugee immigrants, the initial location of immigrants is more likely to
28 be neighbourhoods where people from the same county of origin and some other ethnic
29 groups are concentrated. The analysis confirms the main predictions of spatial assimilation
30 theory with respect to different settlement and mobility patterns for western and non-western
31 immigrant groups on the one hand and between non-western immigrant groups on the other.
32 Western immigrants with a shorter distance from the native Dutch in terms of human capital,
33 relevant language(s), socioeconomic position, and religion, who mainly entered as labour or
34 family migrants, seem less likely to move into a more segregated neighbourhood. Among the
35 immigrant groups with a large community in the Netherlands, Surinamese immigrants differ
36 from Turkish and Moroccan immigrants, reflecting their relatively favourable socioeconomic
37 position, their mastery of the Dutch language, and cultural similarities with native Dutch.
38 Their initial settlement pattern is likely to be unaffected by the ethnic composition of the
39 neighbourhood; their spatial mobility is not in a one-way direction, whereas the subsequent
40 mobility of Turkish and Moroccan immigrants appears to be mainly towards more segregated
41 neighbourhoods. The probability of moving from a more to a less segregated neighbourhood

51
52
53
54
55
56
57
58
59
60

1
2
3 is low for Turkish and Moroccan immigrants, or at least it was in the five years observed. A
4
5 slightly lower tendency of moving into more segregated neighbourhoods for Turkish than for
6
7 Moroccan immigrants might have stemmed from the differences in the socioeconomic
8
9 positions of these two groups.
10
11

12
13 A favourable economic condition of the neighbourhood in terms of low unemployment and
14
15 average high earnings is positively associated more with immigrants who entered the
16
17 Netherlands as labour or family migrants. Looking at the socioeconomic position of the
18
19 immigrant, having a job goes with a greater probability of moving, and these moves are more
20
21 likely to be directed towards less segregated neighbourhoods. We have shown that the impact
22
23 of unemployment on native Dutch and ethnic minorities in the neighbourhood is
24
25 fundamentally different. While more ethnic minority unemployment is associated with a
26
27 greater probability of moving into more segregated neighbourhoods, the unemployment
28
29 among natives seems, on the contrary, to be associated with a greater probability of moving
30
31 towards less segregated neighbourhoods. Finally, those who live in a rented home have a
32
33 greater probability of moving into a more segregated neighbourhood. The housing market
34
35 rigidities seem to generate no different effects across the groups of immigrants who arrived in
36
37 the same year.

2 The multinomial logit model has 4 outcome categories: *native*, *mixed*, *segregated* neighbourhoods and *staying*, which is the reference category. The transition
3 probabilities are separately estimated for the sub-samples of *native*, *mixed*, *segregated* neighbourhoods.

ⁱ The first year upon arrival may be seen as an adjustment year for new immigrants, who often spend some time learning the Dutch language and getting to know the Dutch labour market.

ⁱⁱ For instance; among labour migrants circa 20 percent of non-employed individuals and the presence of people aged under 18 may imply a measurement error.
