**Abstract**

In this paper we discuss the differences between the average marginal effect and the marginal effect of the average individual in sample selection models, estimated by the Heckman procedure. We show that the bias that emerges as a consequence of interchanging the measures, could be very significant, even in the limit. We suggest a computationally cheap approximation method, which corrects the bias to a large extent. We illustrate the implications of our method with an empirical application of earnings assimilation and a small Monte Carlo simulation.

# 1 Introduction

A large amount of applied work using nonlinear microeconomic models has been carried out over the last few decades. One of the important characteristics of these models is their nature, which allows the calculation of individual marginal effects. In general, most empirical studies report one of the two established point estimators for marginal effects: (i) the average of the marginal effects of all individuals in the sample, and (ii) the marginal effect at the sample means. Neglecting their quantitative, and more importantly, conceptual differences is a quite common practice. Greene's (2003) discussion on the marginal effects in binary choice models stresses the fact that in many occasions the asymptotic equivalence of the two measures is taken for granted. Verlinda (2006) shows that arbitrarily interchanging them in a binary probit model could create bias and lead to misleading conclusions, since the two measures estimate different quantities.

In the present paper we discuss the relationship between the two measures in the context of sample selection models, also known as Tobit type II. Provided that one is interested in the average effect over the population rather than in the effect over the average individual, we show that evaluating the derivative at the sample means leads to biased predictions, even asymptotically. Since the other alternative (averaging the marginal effects for the whole sample) could be computationally inefficient, we propose an approximation technique which significantly reduces the bias, without significantly increasing the number of numerical operations. In order to accomplish this, we express the average marginal effect (*AME*) with the Taylor expansion around the mean values of the explanatory variables and prove that the conventionally used marginal effect of the average individual (*MEAI*) is actually equal to the first order Taylor approximation, while the order of magnitude is equal to the asymptotic bias. By shifting to the second order approximation, one can reduce the size of the bias without high computational cost, since the second term of the series is a function of the Hessian and the covariance matrix evaluated at the sample means.

Marginal effects in sample selection models have recently been discussed.

Saha *et al.* (1997a) show that failure to account for changes in the inverse of Mill's ratio leads to biased marginal effects. Hoffmann and Kassouf (2005) introduce unconditional marginal effects in addition to the standard conditional ones. In any case, the clear distinction between *AME* and *MEAI* is necessary regardless of the definition of the marginal effects.

In order to emphasize the necessity of a consistent estimator for the average marginal effects, we present an empirical application of immigrant earnings assimilation using registered data from Sweden. We find that our approach corrects the bias to a large extent, and discuss the policy implications behind this relative difference.

The paper has the following structure. Section 2 briefly describes Heckman's two step procedure. Section 3 introduces the theoretical results of our approach. In section 4 we apply the model to real data, and in section 5 we include Monte Carlo simulations. Section 6 concludes the paper.

## 2 Heckman procedure and marginal effects

Consider the following sample selection (otherwise known as the Tobit type II) model:

$$Y_i^* = \mathbf{X}_i' \beta + \epsilon_i \quad (1)$$

$$H_i^* = \mathbf{Z}_i' \gamma + u_i \quad (2)$$

$$H_i = 1[H_i^* > 0] \quad (3)$$

$$Y_i = Y_i^* \cdot H_i, \quad (4)$$

where  $i = 1, \dots, N$ . Let the latent variables  $Y_i^*$  and  $H_i^*$  denote individual  $i$ 's earnings and hours of work respectively. Assume also that the matrices  $\mathbf{X}_i$  and  $\mathbf{Z}_i$  include various observed individual characteristics, with  $\mathbf{X}_i$  being a strict subset of  $\mathbf{Z}_i$ . Finally, the joint error term  $(\epsilon_i, u_i)$  follows the bivariate normal distribution with correlation coefficient  $\rho$  and normalized variance of the selection equation error term,  $\sigma_u^2 = 1$ . Our primary aim is to estimate the parameter vector  $\beta$  of the earnings equation. We know that strictly positive hours of work is a necessary and sufficient condition for participating in the job market, ie.  $H_i^* > 0$ . Then the participation decision takes the form of a

binary choice, since *working* and *not working* are complementary events, and as such they can be written as the indicator function of the equation above.

Conditioning on the subset of the population that contains the individuals who actually work, the expectation of the earnings given participation would be given by the following formula (Greene, 2003):

$$\begin{aligned} E[Y_i^*|H_i = 1, \mathbf{X}_i, \mathbf{Z}_i] &= E[\mathbf{X}_i'\beta + \epsilon_i|H_i^* > 0] \\ &= \mathbf{X}_i'\hat{\beta} + E[\epsilon_i|u_i > -\mathbf{Z}_i'\gamma] \\ &= \mathbf{X}_i'\hat{\beta} + \hat{\rho}\hat{\sigma}_\epsilon \frac{\phi(-\mathbf{Z}_i'\hat{\gamma})}{1 - \Phi(-\mathbf{Z}_i'\hat{\gamma})}, \end{aligned} \quad (5)$$

where  $\phi(\cdot)$  and  $\Phi(\cdot)$  denote the density and the cumulative distribution of the standard normal distribution respectively. After some notation simplification equation (5) is rewritten as follows:

$$E[Y_i^*|H_i = 1, \mathbf{X}_i, \mathbf{Z}_i] = \mathbf{X}_i'\hat{\beta} + \hat{\rho}\hat{\sigma}_\epsilon\hat{\lambda}_i(\hat{\alpha}_u), \quad (6)$$

where  $\hat{\alpha}_u = -\mathbf{Z}_i'\hat{\gamma}$ , while  $\lambda$  denotes the inverse of Mill's ratio, ie.  $\lambda = \phi/(1-\Phi)$ . It is straightforward that equation (6) cannot be estimated consistently with ordinary least squares (OLS) in the existence of correlation between  $\epsilon_i$  and  $u_i$  ( $\rho \neq 0$ ). On the other hand, although consistent, the maximum likelihood estimator (MLE) constitutes a computationally challenging task. Heckman (1976) introduced a method which can simultaneously handle consistency and computational efficiency. His procedure consists of two separate steps. First, estimate the participation probability by applying a binary probit model

$$P[H_i = 1|\mathbf{Z}_i] = \Phi(\mathbf{Z}_i'\gamma) \quad (7)$$

and use the estimated choice probabilities to calculate  $\hat{\lambda}_i(\hat{\alpha}_u)$ . In the second step, apply OLS on the earnings equation, while perceiving the estimated inverse Mill's ratio as another explanatory variable. Thus, one gets rid of the omitted variable problem that would otherwise emerge, and the estimator of the parameter vector in the target equation becomes consistent.

The *ceteris paribus* estimated marginal effect<sup>1</sup> of an infinitesimal change of an arbitrary individual characteristic  $k$  on individual  $i$ 's earnings is given

<sup>1</sup>A more precise terminology would require defining it as *conditional marginal effect*, since it refers only to the individuals who actually work.

by the following equation for an explanatory variable  $x_{k,i}$ :

$$\widehat{ME}_{k,i} = \frac{\partial E[Y_i^* | H_i = 1, \mathbf{X}_i, \mathbf{Z}_i]}{\partial X_{k,i}} = \hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon \hat{\delta}_i(\hat{\alpha}_u), \quad (8)$$

where  $\hat{\delta}_i(\hat{\alpha}_u) = \hat{\lambda}_i^2(\hat{\alpha}_u) - \hat{\alpha}_u \hat{\lambda}_i(\hat{\alpha}_u)$ . The (total) marginal effect of a variable in a sample selection model can be separated into two parts (Greene, 2003). The *direct effect* ( $\hat{\beta}_k$ ) shows the marginal effect of an explanatory variable on the earnings without taking into account the effect of selectivity in the data. The second term in equation (8) is called *indirect effect* and is a function of the observed individual characteristics. Due to this functional relationship, marginal effects vary across individuals. Omitting the indirect effect would linearize the marginal effect, which is rather convenient in practical terms, but it also creates non-negligible bias. Such a problem would not arise if the estimated correlation coefficient between the errors of the first and second stage estimation equations ( $\rho$ ) were equal to zero (Saha *et al.*, 1997a).

Since policy decisions upon an action that changes an explanatory variable affecting the whole population, the existence of such nonlinearity allows the use of different measures for the marginal effects. In general, economists are interested in the average marginal effect (AME) of this action over all individuals. Using an inconsistent estimator for the *AME* could therefore potentially lead to wrong conclusions and undesired effects of the policy application. A consistent estimator for *AME* is given by the following expression:

$$\widehat{AME}_k = \frac{1}{N} \sum_{i=1}^N \widehat{ME}_{k,i} = \frac{1}{N} \sum_{i=1}^N (\hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon \hat{\delta}_i(\hat{\alpha}_u)). \quad (9)$$

This follows directly from Khinchine's weak law of large numbers. Namely,

$$\text{plim}_{N \rightarrow \infty} \widehat{AME}_k = E[\hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon \hat{\delta}_i(\alpha_u)] = \hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon E[\hat{\delta}_i(\hat{\alpha}_u)] \quad (10)$$

for every  $k$ .

However, due to factors such as computational inefficiency or unavailability of software routines for the calculation of  $\widehat{AME}$ , researchers usually report the marginal effect of the average individual ( $\widehat{MEAI}$ ), which is equivalent to evaluating the marginal effects at the sample means:

$$\widehat{MEAI}_k = \widehat{ME}_{k,i} |_{\mathbf{Z}_i = \bar{\mathbf{Z}}, \mathbf{X}_i = \bar{\mathbf{X}}} = \hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon \bar{\delta}, \quad (11)$$

where  $\bar{\delta} = \hat{\delta}_i(-\bar{\mathbf{Z}}'\hat{\gamma})$ . Notice that  $\widehat{MEAI}$  is a consistent estimator for its population counterpart ( $MEAI$ ),

$$\text{plim}_{N \rightarrow \infty} \widehat{MEAI}_k = E[\hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \frac{\hat{\sigma}_\epsilon}{\hat{\sigma}_u} \hat{\delta}_i(\bar{\mathbf{Z}}'\hat{\gamma})] = \hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon \hat{\delta}_i(\mathbf{M}'\hat{\gamma}) \quad (12)$$

but not for the  $AME$ , since  $E[\hat{\delta}_i(\hat{\alpha}_u)] \neq \hat{\delta}_i(\mathbf{M}'\hat{\gamma})$ . That is,  $\widehat{AME}$  and  $\widehat{MEAI}$  not only differ quantitatively, but also conceptually, since they estimate different things. Hence, the researcher who arbitrarily interchanges them could be led to misleading conclusions.

### 3 Approximating average marginal effects

As we discussed above, interchanging  $\widehat{AME}$  and  $\widehat{MEAI}$  produces bias and leads to inconsistent estimation of  $AME$ . In this section we suggest an approximation method for estimating  $AME$  that is computationally efficient and that significantly reduces the bias emerging from the use of  $\widehat{MEAI}$ . In order to extract the asymptotic bias we expand the Taylor series of  $\hat{\delta}_i(\mathbf{Z}'_i\hat{\gamma})$  around the mean of the explanatory variables,  $\mathbf{M}$ :

$$\begin{aligned} \hat{\delta}_i(\mathbf{Z}'_i\hat{\gamma}) &= \hat{\delta}_i(\mathbf{M}'\hat{\gamma}) + \sum_k \left( \frac{\partial \hat{\delta}_i(\mathbf{Z}'_i\hat{\gamma})}{\partial Z_k} \Big|_{\mathbf{M}} \cdot (Z_{k,i} - M_k) \right) \\ &+ \frac{1}{2!} \sum_{k_1} \sum_{k_2} \left( \frac{\partial^2 \hat{\delta}_i(\mathbf{Z}'_i\hat{\gamma})}{\partial Z_{k_1,i} \partial Z_{k_2,i}} \Big|_{\mathbf{M}} \cdot (Z_{k_1,i} - M_{k_1})(Z_{k_2,i} - M_{k_2}) \right) + \dots \\ &= \hat{\delta}_i(\mathbf{M}'\hat{\gamma}) + \sum_{j=1}^{\infty} \left[ \frac{1}{j!} \sum_{k_1, \dots, k_j} \left( \frac{\partial^j \hat{\delta}_i(\mathbf{Z}'_i\hat{\gamma})}{\partial Z_{k_1,i}, \dots, \partial Z_{k_j,i}} \Big|_{\mathbf{M}} \cdot (Z_{k_1,i} - M_{k_1}) \dots (Z_{k_j,i} - M_{k_j}) \right) \right]. \end{aligned} \quad (13)$$

After plugging the previous expression into equation (8) and taking expectation, we conclude that the  $AME$  is approximated by the following formula

$$\begin{aligned} AME_k &= \hat{\beta}_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon E[\hat{\delta}_i(\mathbf{Z}'_i\hat{\gamma})] \\ &= MEAI_k - \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon \sum_{j=1}^{\infty} \left[ \frac{1}{j!} \sum_{k_1, \dots, k_j} \left( \frac{\partial^j \hat{\delta}_i(\mathbf{Z}'_i\hat{\gamma})}{\partial Z_{k_1,i}, \dots, \partial Z_{k_j,i}} \Big|_{\mathbf{M}} \cdot \Psi_{k_1, \dots, k_j}^j \right) \right] \\ &= MEAI_k + B_k^1(\Psi^1, \Psi^2, \dots) \end{aligned} \quad (14)$$

where  $\Psi_{k_1, \dots, k_j}^j = E[(Z_{k_1,i} - M_{k_1}) \dots (Z_{k_j,i} - M_{k_j})]$  denotes the  $j^{\text{th}}$  order joint moment about the means, while  $B_k^1$  denotes the size of the first order approximation asymptotic bias as a function of the joint moments,  $\Psi^j$ , of the individual characteristics. Therefore by using the  $\widehat{MEAI}_k$  to estimate the  $AME_k$ , one

implicitly takes into account only the first order approximation while neglecting the higher orders, which ultimately leads to bias equal to  $\hat{B}_k^1(\Psi^1, \Psi^2, \dots)$ . If instead one used an additional term of the Taylor polynomial, the *second order approximation of the average marginal effect* ( $\widehat{SOAME}_k$ ) would substitute the  $\widehat{MEAI}_k$ . That would be given by the following formula:

$$\widehat{SOAME}_k = \widehat{MEAI}_k - \frac{1}{2} \hat{\gamma}_k \hat{\rho} \hat{\sigma}_\epsilon \sum_{k_1} \sum_{k_2} \left( \frac{\partial^2 \hat{\delta}_i(\mathbf{Z}'_i \hat{\gamma})}{\partial Z_{k_1, i} \partial Z_{k_2, i}} \Big|_{\bar{\mathbf{Z}}} \cdot \widehat{\text{Cov}}(Z_{k_1, i}, Z_{k_2, i}) \right) \quad (15)$$

By using the second order approximation, which does not significantly increase the number of numerical operations since it only involves the elements of the entrywise product of the Hessian evaluated at  $\bar{\mathbf{Z}}$  and the covariance matrix, one would substantially reduce<sup>2</sup> the bias of the estimates.

In the following section we empirically show that neglecting the bias could create misleading results that could significantly affect the policy implications of the model.

## 4 Empirical applications

We divide our applications into two parts: a study of earnings assimilation of immigrants in Sweden, where we with the use of real data illustrate the necessity of bias reduction in the estimation of marginal effects, and a Monte Carlo simulation where we examine the limiting properties of our approximation technique.

### 4.1 Earnings assimilation of immigrants in Sweden

The economic performance of immigrants is one of the major interests of policy makers in most highly immigrated Western countries. The question in such a study would typically be whether immigrants entered the host country with an earnings difference relative to natives and whether their earnings converge to those of the natives while years since migration ( $YSM$ ) increase (Borjas, 1985, 1999; Longva *et al.*, 2003). Then, based on the answer, policies targeting to

---

<sup>2</sup>The expected second order of magnitude is larger than the third one (Nguyen and Jordan, 2004).

different individual characteristics of the immigrants are designed, in order to adjust the speed of assimilation closer to what is desired by the policy makers.

The data used in the present study comes from the registered nationally representative longitudinal individual data set of Sweden (LINDA), which comes in panel form and is rich in individual socioeconomic characteristics (Edin and Frederiksson, 2001). The principal data sources are income registers and population censuses. Family members are included in the sample only as long as they stay in the household. LINDA contains a sub-panel of about 20 percent of the foreign-born population. The working sample includes 3,136 male individuals, aged 18-65 (1,962 immigrants<sup>3</sup> and 1,174 natives) followed for 11 years from 1990 to 2000.

Table 1 shows the mean characteristics of the sample. The earnings and the income from other sources are considerably higher among natives than among immigrants. Natives are more likely to be employed (0.82 vs. 0.57), are slightly older (38.4 vs. 37.1), but are also less likely to be married (0.39 vs. 0.43) and they have fewer children at home (0.44 vs. 0.48). They also acquire a higher level of education: 76 percent of natives are high school graduates, while the number is 71 percent among immigrants.

- *Table 1 about here*

The immigrant arrival cohorts are classified into five year intervals except for the first and the last ones, which include the years before 1970 and the 1995-2000 period (six years), respectively. These two cohorts are slightly underrepresented in the sample (7 and 6 percent respectively). The immigrants are categorized according to their country of origin as follows: Nordic countries, USA, Western countries except USA (EU-15, Canada, Australia and New Zealand), Eastern Europe, Middle East, Asia, Africa, and Latin America.

Based on working indicators in the data, an employment dummy is defined that takes a value of 1 if the individual is employed and 0 otherwise. The earnings variable used in the study is obtained from the national tax registers and is measured in thousands of Swedish Kroner (SEK) per year, adjusted to 2000 prices.

---

<sup>3</sup>We define an immigrant as an individuals who was born abroad (first generation).

The model specification for the immigrants is given by the following standard sample selection model:

$$\begin{aligned} Y_i^* &= \mathbf{X}_i' \beta + \phi AGE_i + \delta YSM_i + \sum_j \psi_j C_i^j + \sum_k \theta_k \Pi_i^k + \epsilon_i \quad (16) \\ H_i^* &= \mathbf{Z}_i' \gamma + u_i \\ H_i &= 1[H_i^* > 0] \\ Y_i &= Y_i^* \cdot H_i, \end{aligned}$$

where  $i$  denotes each cross section, and  $Y^*$  is the natural logarithm of the latent earnings. The individual characteristics included in the  $\mathbf{X}_i$  matrix are individual  $i$ 's number of children, marital status, size of permanent residence, education, and geographical origin. The variables  $AGE$  and  $YSM$  denote the age and the years since migration respectively<sup>4</sup>. Finally  $C_i^j$  and  $\Pi_i^k$  are indicator variables for the  $j$ -th immigrant arrival cohort and the  $k$ -th year.  $C_i^j$  becomes 1 if the individual arrived at the  $j$ -th cohort and 0 otherwise. Similarly,  $\Pi_i^k$  takes the value 1 if the individual is observed in the  $k$ -th period, and the value 0 otherwise. The  $\mathbf{Z}_i$  matrix includes the same characteristics plus the logarithm of non-labor income<sup>5</sup>. The model specification for the natives does not differ from the one estimated for the immigrants, with the exception of the variables that are not applicable, e.g. years since immigration, arrival cohort and geographical origin.

The assimilation model given by (16) aims to identify the three important effects (aging, arrival cohort and period effect) on the earnings assimilation simultaneously. However, this model is not identified in any given cross section, since the calendar year in which the cross section is observed is the sum of  $YSM$  in the host country and the calendar year in which the individual immigrated. Thus the identification restriction imposed in the present study is that the period effect in the immigrant earnings equation is equal to that of the natives ( $\Pi_i^I = \Pi_i^N, \forall i = 1, \dots, 11$ ), which is a standard assumption in the assimilation literature (Borjas, 1985, 1999).

<sup>4</sup>The exact functional forms for age and years since migration are quadratic. The second order terms are omitted for notation simplicity purposes.

<sup>5</sup>The exclusion restriction adopted in this paper is that the non-labor income affects the probability of being employed but not the earnings.

The estimation results and the bias analysis for the probit equation (first step) and the target equation (second step) are presented in tables 2 and 3 respectively, along with the  $\widehat{AME}$ , the  $\widehat{MEAI}$ , the  $\widehat{SOAME}$  and the first and second order bias ( $\widehat{FOBIAS}$  and  $\widehat{SOBIAS}$ ), which denote the difference between the consistent estimator  $\widehat{AME}$  and its first ( $\widehat{MEAI}$ ) and second order ( $\widehat{SOAME}$ ) approximations respectively. For example, the  $\widehat{AME}$  for the variable *AGE* for the immigrants is estimated to 0.153, while the corresponding  $\widehat{MEAI}$  and  $\widehat{SOAME}$  are equal to 0.235 and 0.175 respectively, which constituting a 73 percent improvement of the bias.

- *Table 2 about here*
- *Table 3 about here*

Taking a closer look at the first and second order bias estimates of the selection and the earnings equation (tables 2 and 3 respectively), one can easily notice the rather significant improvement in all variables, not only in relative but also in absolute terms. This becomes even more worth mentioning since it is observed in the key variables. For instance, having a university degree improves the earnings of the immigrants by 0.340 log points, according to the  $\widehat{AME}$ . On the other hand, using the  $\widehat{MEAI}$  yields an estimate equal to 0.370 log points. Finally, the  $\widehat{SOAME}$  is equal to 0.348, which is substantially closer to the  $\widehat{AME}$  (73 percent bias correction).

A really interesting result, though not surprising given the structure of the Taylor series, is that the percentage change in the bias level by shifting to the second order approximation remains constant across explanatory variables. Table 4 shows the size of the relative improvement when the second order approximation is used.

- *Table 4 about here*

As we mentioned above, the hypothesis that one is usually willing to test in this specific type of study is *whether the earnings of the immigrants catch up with those of the natives with enough years spent in the host country, and if so how long this assimilation process takes*. Assume that the aging variables

are defined as a function of time ( $AGE(t)$  and  $YSM(t)$ ). Then the relative earnings for immigrant  $i$  with respect to native  $j$ ,  $t$  years after migration, are given by the following equation:

$$\begin{aligned}\Delta Y_{i,j}(t) &= E^I[Y_i|H_i = 1, AGE(t_0 + t), YSM(t), \mathbf{X}_i, \mathbf{Z}_i] \\ &- E^N[Y_j|H_j = 1, AGE(t_0 + t), \mathbf{X}_j, \mathbf{Z}_j],\end{aligned}\quad (17)$$

where  $t_0$  is the age at migration<sup>6</sup>, while  $E^I$  and  $E^N$  denote the conditional expectations of the assimilation model of the immigrants and the natives respectively. Evaluating  $\Delta Y_{i,j}(t)$  at  $t = 0$  yields the initial earnings difference, otherwise called entry effect upon arrival.

Then the estimated marginal rate of assimilation ( $\widehat{MRA}$ ), which shows the rate of earnings convergence between the  $i$ -th immigrant and the  $j$ -th native at time  $t$  (Barth *et al.*, 2004), is given by the following equation:

$$\widehat{MRA}_{i,j}(t) = \frac{\partial E_i^I}{\partial t} - \frac{\partial E_j^I}{\partial t}.\quad (18)$$

or in terms of marginal effects:

$$\widehat{MRA}_{i,j}(t) = \widehat{ME}_{AGE,i}^I(t) + \widehat{ME}_{YSM,i}^I(t) - \widehat{ME}_{AGE,j}^N(t)\quad (19)$$

We thus reach a point where the marginal effects are in question again. Given the fact that we are interested in the average total years of assimilation ( $\widehat{ATYA}$ ), one should estimate the average marginal rate of assimilation ( $\widehat{AMRA}$ ). Namely,

$$\begin{aligned}\widehat{AMRA}(t) &= \sum_{i=1}^I \sum_{j=1}^J \frac{1}{I} \frac{1}{J} (\widehat{ME}_{AGE,i}^I(t) + \widehat{ME}_{YSM,i}^I(t) - \widehat{ME}_{AGE,j}^N(t)) \\ &= \frac{1}{I} \sum_{i=1}^I \widehat{ME}_{AGE,i}^I(t) + \frac{1}{I} \sum_{i=1}^I \widehat{ME}_{YSM,i}^I(t) - \frac{1}{J} \sum_{j=1}^J \widehat{ME}_{AGE,j}^N(t) \\ &= \widehat{AME}_{AGE}^I(t) + \widehat{AME}_{YSM}^I(t) - \widehat{AME}_{AGE}^N(t),\end{aligned}\quad (20)$$

where  $I$  and  $J$  denote the total number of immigrants and natives respectively. One can similarly calculate the estimators for the marginal rate of assimilation

<sup>6</sup>The entry age in the present study is assumed to be constant across immigrants and equal to 20.

for the average individual ( $\widehat{MRAAI}$ ) and the second order approximation of the average marginal rate of assimilation ( $\widehat{SOAMRA}$ ), by substituting the corresponding marginal effects in equation (20).

Then the estimator of the average total years of assimilation ( $\widehat{ATYA}$ ) is the upper limit that equates the following integral with the average initial earnings difference:

$$\int_0^{\widehat{ATYA}} \widehat{AMRA}(t) dt = \Delta Y(0) \quad (21)$$

Table 5 shows the estimation results. The  $\widehat{ATYA}$  is reported in the first column for each group of immigrants. According to this estimator, the earnings of the immigrants from for example Africa catch up to the level of the natives *on average* 25.3 years after arrival. The second column of the table reports total years of assimilation for the average immigrant ( $\widehat{TAAI}$ ). The corresponding estimate for the *average* African immigrant is 23.6 years, which is 1.7 years shorter than the  $\widehat{ATYA}$ . Finally, by using the method we propose in the present paper, the second order approximation of the average total years of assimilation ( $\widehat{SOATYA}$ ) yields an estimate of 24.4 years, which is 54 percent closer to the targeted result.

- *Table 5 about here*

## 4.2 Monte Carlo simulation

As we have already discussed, the bias that emerges when using the  $\widehat{MEAI}$  as a point estimator of the  $AME$  is not a consequence of a small sample, which would disappear in the limit. Regardless of the sample size, the second order approximation leads to bias reduction compared to the first one. The purpose of this section is to provide empirical evidence for the size of the bias reduction through a Monte Carlo experiment.

- *Table 6 about here*

Assume a standard sample selection model of the form of equation (1), with  $\mathbf{X}_i$  being a singleton and  $\mathbf{Z}_i = (Z_{1,i}, Z_{2,i})$  coming from the bivariate normal distribution with mean  $\mu_i = (\mu_1, \mu_2)$  and covariance matrix  $\Sigma$ . Assume also

the following parameter values:  $\beta = 1$ ,  $\gamma = (3, -2)$ ,  $\sigma_\epsilon = 0.5$ ,  $\sigma_u = 1$ ,  $\rho = -0.8$ ,  $\mu = (0.5, 1.5)$ , and  $\Sigma = \begin{bmatrix} 0.5 & -0.1 \\ -0.1 & 1 \end{bmatrix}$ . By using pseudo-random numbers, we then repeatedly evaluate the first and the second order bias, while increasing the sample size in steps of 100 observations. The results are presented in table 6.

- *Figure 1 about here*

Figure 1 illustrates the same point as table 6, namely that it becomes clear that the bias that emerges when using the  $\widehat{MEAI}$ , is corrected to a rather large extent, without a corresponding computational cost. Notice that bias reduction is observed not only for small samples, but also asymptotically.

## 5 Concluding discussion

In this paper we discuss the differences between two point estimators of the marginal effect of an explanatory variable on the population, in a sample selection model estimated by Heckman's two step procedure. We show that contrary to a rather widespread perception that neglects any differences between them, the average marginal effect is significantly different from the marginal effect of the average individual, even asymptotically. Thus, it should be clear that there is not only a quantitative distinction but also a conceptual one between these measures. Given that the usual aim is to extract information about the average effects on the population, a clear bias would emerge if using the marginal effect of the sample average individual. Hence, we suggest an approximation method based on the Taylor expansion, which should correct the bias to a rather remarkable extent, while increasing the number of computational operations relatively little. Such an example is presented in the paper, along with a Monte Carlo experiment, both supporting the previous argument. Before closing, we would like to make clear that we do not argue in favor of the average marginal effect and against the marginal effect of the average individual. Instead, our aim is to stress that once the average marginal effect has been chosen as an informative tool for policy making, the sample marginal effect of the average individual provides inconsistent estimations which can be

corrected to a large extent by the proposed method.
