March 2007

Abstract

The paper analyses the relationship between regional mobility and earnings for different groups of workers. Using a large panel microdata set we find negative earnings differentials of movers in the year before migration and strong evidence for significant wage gains through mobility. A decomposition of Blinder/ Oaxaca type reveals different group-specific rewards effects suggesting a positive post-mobility wage differential of movers over the incumbent workforce for some groups irrespective of the region of destination. The existence of a general wage growth effect of mobility appears to be robust and cannot be explained by the time-invariant part of unobserved heterogeneity.

Keywords:

Inter-regional mobility, migration wage differentials, unobserved heterogeneity, propensity score matching.

JEL-classification: J61, R23

1 Introduction

Given the importance of the economic policy debate on labour market flexibility and labour market reforms especially in continental Europe, there is a renewed interest in the various dimensions of labour mobility. Workers move within and between occupations, firms and industries. Some of these moves take place within the same region while others are connected with a change in the region where the workplace is located. The pioneering studies of MINCER and JOVANOVIĆ (1981) and BARTEL and BORJAS (1981) deal with the correlation of job mobility and wages. Aspects like geographical, industrial and occupational mobility are taken as components of overall job mobility and not treated separately. Both studies stress the consequences of labour turnover for the worker's experience rating: while young workers experience significant wage gains when changing the employer voluntarily, it cannot be predicted how differences in mobility during the first ten years of working life affect the workers' lifetime wage path.

Following these two seminal contributions to research in labour mobility, much effort has been devoted to assessing the relationship between early job mobility and wages also in the context of the theory of general and firm-specific human capital¹ (e.g. BARTEL, 1980; MINCER, 1986; ANTEL, 1991; TOPEL and WARD, 1992)². All these studies measure the immediate gains of movers typically as between-job wage growth. Mobility reflects the workers' search for better jobs. Even in the early literature this was associated with the realization of individual comparative advantages (JOHNSON, 1978), high-quality job matches (JOVANOVIĆ, 1979) or simply a move to better paid jobs (BURDETT, 1978).

The cited studies stress the positive effects of job mobility on wages. However, there may also be negative effects. Typically, workers (and firms) invest in firm-specific human capital and the individual wage increases with the stock of acquired skills that makes the worker more productive within the firm. By changing the employer the worker can no longer profit from his or her firm-specific skills. Some empirical evidence supports this view. LIGHT and MCGARRY (1998, p.276), for instance, find "... that workers who undergo persistent mobility have lower log-wage paths than less mobile workers". This result is corroborated by more recent studies like MUNASINGHE and SIGMAN (2004).

1
2
3 Another strand of the literature explicitly deals with the determinants of job changes (FARBER, 1999)
4 and the differences in occupational mobility patterns (HEITMUELLER, 2004).
5
6
7

8 The regional dimension of mobility has been stressed by a number of studies following the pioneer
9 work of HARRIS and TODARO (1970). ANTOLIN and BOVER (1997) and PISSARIDES and
10 WADSWORTH (1989)³, among others, examine how unemployment affects the inter-regional migra-
11 tion of labour. The employment prospects of unemployed migrants are highlighted in PEKKALA and
12 TERVO (2002), for instance. The effect of migration on post-move employment (e.g. TERVO, 2000)
13 can also be considered within the context of family decisions (see, for instance, NIVALAINEN,
14 2005). In contrast to the vast literature on the economic consequences of immigration (e.g. BORJAS,
15 1994; HAISKEN-DENEW, 1996), less effort has been devoted to the wage effect of inter-regional
16 mobility within a country. Exceptions are especially found for Scandinavian countries. NAKOSTEEN
17 and WESTERLUND (2004) for Sweden and PEKKALA (2002) for Finland both observe significant
18 income gains from migration. For Germany, Jennifer HUNT (2004) investigated migration streams
19 using the German Socio Economic Panel (GSOEP). She stresses the importance of inter-state migra-
20 tion without changing the employer. According to her results, this group represents about one fifth of
21 all migrants and is characterized by higher skills and has higher pre-move wages than the group of
22 non-migrants.

24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40

41 The impact of migration on wages has been considered explicitly from a spatial job search perspective
42 by DETANG-DÉSSENDRE, DRAPIER and JAYET (2004) using data for young Frenchmen. Taking
43 the possibility of self-selection into account they find no selection effect for low-educated migrants
44 and a positive one for highly-educated ones, especially for those who move to Ile-de-France.
45
46
47
48
49

50 The specific impact of rural-urban mobility on the level and growth rates of individual wages has been
51 analyzed by GLAESER and MARÈ (2001) with U.S. data. They find that workers moving from rural
52 to metropolitan areas experience significant wage gains immediately after migration, which supports
53 the existence of an urban wage premium. However, although movers benefit from migration to metro-
54 politan areas, they typically fall behind the incumbent urban workforce. This wage disadvantage is
55 gradually reduced by a wage-growth effect induced by migration. GLAESER and MARÈ (2001) argue
56 that these effects stem from faster accumulation of human capital in cities leading to a rise in the urban
57
58
59
60

1
2
3 wage premium over time. Hence, wages are highest for individuals staying in these areas for a longer
4
5 period.
6

7
8 The immediate wage gains after rural-urban migration corroborate the existence of a so-called *wage-*
9
10 *level effect* being associated with the migration of workers to cities. The wage level hypothesis can be
11
12 justified by arguing that wages in cities are higher than in rural areas because of higher demand in
13
14 cities and cheaper inputs due to the proximity of suppliers of intermediate goods, for example.⁴ The
15
16 hypothesis would imply a marked decline in wages if workers left the metropolitan area. According to
17
18 GLAESER and MARÈ (2001), however, this is not observed empirically. Workers typically face no
19
20 wage losses if they move away from cities. This is in accordance with PERI (2001), who presents a
21
22 theoretical model explaining why highly-educated young workers are attracted to big cities and why
23
24 some of these workers move to less dense areas when old.
25
26

27
28 The aim of our paper is to investigate the relationship between inter-regional mobility and earnings
29
30 from several perspectives. Controlling for their observed characteristics such as skills, experience and
31
32 gender, we examine the wage differentials between mobile workers and their immobile counterparts.
33
34 Like GLAESER and MARÈ (2001) we analyze the earnings of movers before and after migration in
35
36 order to identify the wage level effect of mobility. In contrast to these authors, however, we do not
37
38 restrict our analysis to the wage effects for migrants to or out of metropolitan areas, but rather study
39
40 movers between other types of regions as well. This enables us to differentiate between a general ef-
41
42 fect of inter-regional mobility and a specific effect being tied to metropolitan areas as the region of
43
44 destination. The existence of a significant general effect would reduce the magnitude of the rural-to-
45
46 urban migration wage premium found by these authors.
47
48

49
50 The remainder of the paper is organized as follows: The next section deals with a description of our
51
52 data source, methodological issues and basic definitions. Section 3 presents some descriptive evi-
53
54 dence. Section 4 introduces our econometric model. By using a decomposition technique, the migra-
55
56 tion wage differential is analyzed in section 5. Section 6 checks the robustness of our results using
57
58 alternative empirical strategies and section 7 concludes.
59
60

2 Data and basic definitions

2.1 Data

The data used in this paper is a one percent random sample from the employment register of the Institute of Employment Research, Nuremberg (IAB). The data base (IABREG) contains all workers, employees and trainees with the obligation of paying social insurance contributions and represents about 80 percent of the total workforce. Not included in the data are, for instance, civil servants, marginal employed persons, students enrolled in higher education, workers under apprenticeship, volunteers and family workers. The employment register contains detailed histories for each worker's time in employment. Here we consider all persons aged 16 to 70 years who were employed on 30th June of each year. The key variable for our analysis is gross daily wages⁵ being gathered in the register for administrative purposes. Due to legal sanctions for the employer in cases of misreporting, the variable can be considered highly reliable. Because of the contribution assessment ceiling in the German social security system, however, the earnings information is top coded. This concerns less than 10 percent of all observations. The likelihood of censoring increases with age and education. Moreover, the data set gives information on personal characteristics of workers like gender, age and education as well as some basic information about the employer (industry affiliation, location, firm size).

In our analysis the qualification of workers will be subdivided into three categories:

- *low-skilled*: persons with no occupational qualification regardless of which schooling level, that is, with or without upper secondary education (*Abitur*);
- *skilled*: persons with an occupational qualification whether they have an upper secondary education or not;
- *highly-skilled*: persons with upper secondary education holding a university degree or higher education diploma.

The regional information in the data refers to the location of the firm or workplace and not the residence of a worker. Using a classification scheme of the *Bundesanstalt für Bauwesen und Raumordnung* (BBR) we differentiate between nine types of regions at NUTS3 (county) level. The classifica-

1
2
3 tion scheme of the BBR distinguishes between areas with large agglomerations, areas with features of
4 conurbation and areas of rural character. Within areas comprising large agglomerations, the classifica-
5 tion scheme distinguishes between metropolitan core cities (BBR1), highly urbanized districts (BBR2)
6 in the surroundings of those cities, urbanized districts (BBR3) and rural districts (BBR4). The second
7 category contains core cities (BBR5) in regions with intermediate agglomerations, their urbanized
8 surroundings (BBR6) and rural districts (BBR7). In the regions of rural character the differentiation is
9 between urbanized districts (BBR8) and rural districts (BBR9).⁶ The firm size information in the data
10 is divided into eight categories (see Appendix, *table A2*).

11
12 Because there are still large structural differences in the labour market and the mobility pattern be-
13 tween the eastern and the western part of Germany⁷, we restrict the analysis to workers in pre-unified
14 Germany. Beyond this we drop part-time workers, workers with more than one job and those for
15 whom we have no valid information concerning earnings, age, qualification or the region type they
16 work in (see Appendix, *table A3* for data selection).

17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 32 33 34 35 36 **2.2 Basic definitions**

37
38 Following GLAESER and MARÈ (2001) we concentrate on the spatial dimension of mobility. Like
39 these authors our approach stresses the role of the characteristics of regions for wage determination in
40 order to catch possible agglomeration effects. Throughout the paper we therefore define mobility of
41 employed workers as a change in the BBR-region type where the workplace is located.⁸ We disregard
42 workers who are not observed at the cut-off date for two succeeding years. Hence we exclude observa-
43 tions of mobile workers who were not employed in period $t=0$, but employed in $t=1$ (“drop-ins”), those
44 who were employed in period $t=0$, but not in $t=1$ (“drop-outs”), and, of course, those who were unem-
45 ployed or out of the labour force for both periods. We construct a (0,1)-dummy variable that indicates
46 whether or not a person is employed in a different type of region in period $t=1$. In $t=0$ those who are
47 going to reveal their mobility in the next period are called *future movers* (FM). After having moved to
48 a workplace in a different region type, this group of workers is addressed in period $t=1$ as *current*
49 *movers* (CM), or simply *movers*. Correspondingly, workers who do not change the type of region
50
51
52
53
54
55
56
57
58
59
60

1
2
3 where the workplace is located from period $t=0$ to $t=1$ are called *future stayers* (FS) in period $t=0$ and
4
5 *current stayers* (CS), or simply *stayers* in $t=1$.
6
7

8 *Table 1* gives some basic information on the number of observations for movers and stayers in our
9
10 sample. For the time period 1993 to 1997 the share of (current) movers in the total number of workers
11
12 is fairly constant at 2.5 percent. In the early stage of the re-unification process (1991 and 1992) the
13
14 share of mobile workers is higher (2.8 to 3.0 percent). In absolute numbers, the group of movers com-
15
16 prises between 3,900 and 5,200 persons per year.
17

18
19 +++++ Insert Table 1 about here +++++
20
21

22 23 24 25 **3 Basic facts about movers and stayers**

26 27 28 29 **3.1 The mover/ stayer-wage differential**

30
31
32 *Figure 1* shows the raw wage differential of movers over stayers and a 95 percent confidence interval
33
34 for 1991 to 1997. It turns out that the differential varies to some extent but is positive in all years. The
35
36 differential is lowest (0.3 percent) and statistically not significant in the re-unification boom year 1992
37
38 and highest in 1996 (3.8 percent). The average value is about 2 percent and there appears to be no
39
40 clear time trend.
41

42
43 +++++ Insert Figure 1 about here +++++
44

45
46 Comparing the average wage of mobile and immobile workers *before* migration gives a completely
47
48 different picture. As shown in *figure 2*, the corresponding wage differential of prospective movers is
49
50 negative. This indicates that mobile workers have a wage disadvantage in the year before migration
51
52 compared to their immobile counterparts. The differential is especially high in the early nineties,
53
54 where the corresponding raw wage differential reaches almost -7 percent. Between 1993 and 1996 the
55
56 raw differential is in the range of -1.5 to -2.5 percent. Assuming that differences in personal charac-
57
58 teristics between the group of movers and stayers are stable over time, one can combine the informa-
59
60 tion contained in *figure 1* and *2* to conclude that moving entails a positive wage effect. Since movers
can substantially improve their relative wage position immediately after getting a workplace in a dif-

1
2
3 ferent type of region, there is first evidence of a general “wage level” effect of mobility. At this stage
4
5 of analysis, however, it is not clear whether prospective movers are “underpaid” before moving and try
6
7 to offset their disadvantage by mobility, or exhibit characteristics that are responsible for a lower
8
9 wage. The negative wage effect before moving might also be due to the famous Ashenfelter dip (see
10
11 ASHENFELTER, 1978). This would indicate that workers reduce their search effort in the region of
12
13 origin because the migration decision has already been taken.
14

15
16
17 +++++ Insert Figure 2 about here +++++
18

19 20 21 **3.2 Differences in the characteristics of movers and stayers** 22

23
24 Up to now the raw wage differential of movers and stayers was considered without taking possible
25
26 differences in observed characteristics of these groups into account. In order to present some basic
27
28 information on these differences we have chosen the year 1997.⁹
29

30
31 With respect to gender, it can be seen from *table 2* that more than 71 percent of all movers are male
32
33 workers, while the share of male workers in the reference group of stayers is less than 67 percent. The
34
35 corresponding over-representation of male workers in the group of movers is also reflected by the
36
37 measure of concentration.¹⁰ As can be expected by migration theory, movers and stayers also differ in
38
39 their skills. Compared to the reference group, movers are more likely to be skilled (77.8 percent versus
40
41 75.0 percent) or highly-skilled (11.3 percent versus 7.9 percent) as shown in *table 2*.¹¹ These discrep-
42
43 ancies are mirrored by a large difference of shares in the low-skilled category (10.8 percent versus
44
45 17.1 percent).
46

47
48 +++++ Insert Table 2 about here +++++
49

50
51 Further aspects concern the workers’ potential on-the-job experience¹², the region type and firm size.
52
53 Here we consider three experience, four region type and three firm size categories.¹³ *Table 2* shows
54
55 that movers are distinctly less experienced than stayers: 28.5 percent of movers have less than 10
56
57 years’ potential work experience, while the share of stayers in that low experience category is 18.6
58
59 percent only. In the intermediate experience category (10 to 19 years) the share of movers exceeds that
60
of stayers by about 7 percentage points, while the share of movers with high experience is 32.3 percent

1
2
3 compared to 49.5 percent for stayers. The two groups also differ with respect to the firm size of their
4
5 employers. Compared to stayers, movers are more likely to be employed in small firms (45.5 percent
6
7 to 37.1 percent) and less in large ones (17.5 percent to 26.8 percent).
8
9

10 The regions of destination for more than half of the mobile workers are metropolitan cities and their
11
12 highly urbanized surroundings (RT1). According to the measure of concentration, the share of movers
13
14 exceeds the share of the reference category only slightly.¹⁴ The over-representation of movers is more
15
16 pronounced for less urbanized regions in the farther periphery of metropolitan cities (RT2). At the
17
18 same time, mobile workers choosing peripheral rural areas (RT4) as their region of destination are
19
20 strongly under-represented.
21
22

23 To sum up, we find marked differences in the characteristics of mobile and immobile workers. Movers
24
25 tend to be younger and more skilled than their immobile colleagues. Males and workers in smaller
26
27 firms are also over-represented in the group of movers. Moreover, mobile workers disproportionately
28
29 tend to move to less urbanized regions in the farther periphery of metropolitan cities.
30
31
32
33
34

35 **4 Econometric estimates based on earnings functions**

36 **4.1 Outline of the estimation approach**

37
38
39 In order to analyze the wage differential between mobile and immobile workers more rigorously we
40
41 estimate a Mincer-type wage equation for each of the four groups defined above.¹⁵ More specifically,
42
43 for each group we assume a linear relationship between the log earnings and several explanatory vari-
44
45 ables measuring skill, (potential) experience and other characteristics of the worker and the employer.
46
47 Potential experience (*EXP*) enters the wage equation in linear and quadratic form to capture a non-
48
49 linear (concave) wage/ experience profile. We measure the effect of six skill/ gender categories by
50
51 corresponding (0,1)-dummy variables, where $DSKILL_n$ ($n = 1, \dots, 3$) indicate male workers with low,
52
53 intermediate and high skills, respectively, while $DSKILL_n$ ($n = 4, \dots, 6$) stand for the corresponding
54
55 three skill categories of female workers. The effect of firm size on earnings is captured by eight differ-
56
57
58
59
60

entiated firm-size (0,1)-dummy variables (*FIRMSIZE*) with the smallest category (less than 6 workers) chosen as a reference.¹⁶ In addition, our estimation approach includes eight (0,1)-dummy variables for the type of region (*REGIONTYPE*) taking metropolitan cities (BBR1) as the reference category. Moreover, we introduce interaction effects between the workers' experience with gender and qualification¹⁷. The equation to be estimated can be formulated as

$$\begin{aligned} \ln w_i^\theta = & \alpha_0^\theta + \alpha_1^\theta EXP_i + \alpha_2^\theta EXP_i^2 + \alpha_{3,n}^\theta \sum_{n=2}^8 FIRMSIZE_{n,i} + \alpha_{4,n}^\theta \sum_{n=2}^9 REGIONTYPE_{n,i} \\ & + \alpha_{5,n}^\theta \sum_{n=2}^6 DSKILL_{n,i} \\ & + \text{interactions of experience and experience squared} \\ & \text{with gender and qualification} + u_i^\theta \end{aligned} \quad (1)$$

The dependent variable w_i^θ stands for earnings of individual i within a specific group of workers

$\theta = \{CM, FM, CS, FS\}$. The error term u_i^θ is assumed to be independently and normally distributed.

To account for top coding in the data, we use the Tobit estimation method.

4.2 Estimation results

Table 3 contains the results of the Tobit estimates for the successive years 1996 and 1997¹⁸. Sign and magnitude of the coefficients correspond to theoretical expectations. The Pseudo- R^2 ranges between 0.38 and 0.43 and the standard error is about 1/3 in all cases. The Likelihood-Ratio Test indicates a significant influence of the explanatory variables at the very high significance level. The number of observations is 3,899 for the group of movers whereof 386 observations or 9.9 percent are right-censored in the year 1996, and 436 (11.2 percent) in 1997. For the group of stayers we have 152,999 observations including 14,453 right-censored observations in 1996 and 149,018 in 1997, thereof 13,895 right-censored.

+++++ Insert Table 3 about here +++++

With respect to the estimated coefficients we observe fairly similar results for the group of future and current movers on the one hand and future and current stayers on the other. There are, however,

1
2
3 marked differences *between* movers and stayers in general. First, the coefficients of the skill/ gender
4
5 dummy variables for movers are somewhat lower in magnitude than for stayers. The same is true for
6
7 the coefficients capturing the firm-size differential. Second, for stayers the coefficients for the region
8
9 type are significantly negative and increase in absolute values for more peripheral regions. For the
10
11 group of movers we find a significant positive effect for BBR2. According to this result, movers ex-
12
13 hibit a positive wage differential in the environs of metropolitan cities compared to the centre itself.
14
15 Third, the estimated coefficients of the experience variable are lower for future and current movers
16
17 than for stayers. However, for movers there is a marked positive interaction effect with qualification.
18
19 By contrast, the corresponding interaction effect is not significant for future stayers and even signifi-
20
21 cantly *negative* for current stayers. Fourth, the interaction of experience and gender is negative in all
22
23 cases, but lower in magnitude and statistically not significant for movers.
24
25
26

27
28 To summarize, the coefficients of wage equations for movers and stayers exhibit some marked differ-
29
30 ences leading to the conclusion that both groups not only differ in characteristics but also in the way
31
32 these characteristics are remunerated by the employers.
33
34
35

36 37 **5 Decomposition of the mover/ stayer-wage differential**

38 39 40 41 **5.1 Decomposition method**

42
43
44 Of course, the estimated coefficients of the dummy variables in eq.(1) depend on the choice of refer-
45
46 ence group. The coefficients would change, for example, if highly-skilled female workers were taken
47
48 as the reference for the skill/ gender category instead of low-skilled male ones. Therefore, it is prefer-
49
50 able to base the interpretation of the results on standardized coefficients that do not depend on the
51
52 specific choice of the reference group. Following a method originally proposed by GREENE and
53
54 SEAKS (1991), we therefore re-calculated the estimated coefficients in order to obtain effects relative
55
56 to the weighted average in the aggregate economy.¹⁹ For the decompositions below we use the some-
57
58 what broader classifications as in Section 3.2. Considering six skill/ gender categories, four region
59
60 types, three experience and firm size categories yields a total of $6 \times 4 \times 3 \times 3 = 216$ cells. The means

1
2
3 of the explanatory variables are calculated for each cell. With this information and the estimated coef-
4
5 ficients of the wage equations it is straightforward to compute the average wage for each cell as pre-
6
7 dicted by our model. We then use a BLINDER (1973)/ OAXACA (1973) technique for a group-
8
9 specific decomposition of the raw wage differential between movers and stayers.²⁰
10
11

12 13 **5.2 Analysis of the mover/ stayer wage differential** 14

15
16 In order to investigate the net effect of work place mobility by comparing the wage of movers in the
17
18 year after migration to the wage of their immobile counterparts in the region of destination, we con-
19
20 sider decompositions by region type, skill category and experience.²¹ *Table 4* contains the results at
21
22 alternative levels of aggregation. Differentiation by region type only shows that earnings of movers
23
24 and stayers vary substantially across types of regions. Immobile workers earn 6.8 percent above the
25
26 national average in metropolitan regions (RT1), but 11.7 percent below in rural areas (RT4). While in
27
28 metropolitan cities the spatial wage differential of movers is similar to that of stayers (6.1 percent), it
29
30 differs markedly in region types with lower population density (RT2 and RT4). According to our esti-
31
32 mates, earnings of immobile workers are well below the total average in RT2 (-6.5 percent), while
33
34 those of movers exceed the average by 1.5 percent. The corresponding values for stayers and movers
35
36 in rural regions (RT4) are -11.7 and -3.5 percent respectively. At first glimpse the results seem to
37
38 suggest that spatial wage differentials vary distinctly between mobile and immobile workers. How-
39
40 ever, these patterns might be strongly influenced by the characteristics of both groups.
41
42
43

44
45 +++++ Insert Table 4 about here +++++
46
47

48 Therefore, a deeper analysis requires the consideration of skill and experience categories for each type
49
50 of region. We first take differences in the skill level into account. From the right panel of *table 4* it is
51
52 apparent that highly-skilled workers are clearly over-represented in core cities and their vicinities.
53
54 Note that more than 10 percent of incumbent workers in RT1 are highly-skilled, while the correspond-
55
56 ing share of the top skill category is distinctly lower in other region types (between 4 and 6 percent).
57
58

59 A closer inspection of *table 4* shows that, irrespective of the region type, the share of movers belong-
60
ing to the highest skill category exceeds that of stayers, while the opposite is true for low-skilled

1
2
3 workers. At this level of differentiation, the estimated difference in movers' and stayers' earnings is
4
5 predominantly negative in the urbanized regions (RT1 and RT3), and mostly positive in more rural
6
7 ones (RT2 and RT4). Depending on the region type, the average earnings of low-skilled workers in the
8
9 reference group of stayers are between 15 percent and 30 percent below the total average. For the in-
10
11 termediate skill category we find earnings between 9 percent below and 5 percent above the average.
12
13 By contrast, the earnings of the highly-skilled are between 40 and 54 percent above average. Thus the
14
15 wage advantage of movers over stayers tends to increase with the skill level. This is in accordance
16
17 with theoretical predictions.
18
19

20
21 The finest form of decomposition is obtained by additionally considering experience. Differentiating
22
23 by experience turns out to be crucial for understanding the effects of moving on wages. Except for
24
25 highly experienced low-skilled workers, movers to RT2, RT3 and RT4 are always better off than their
26
27 immobile counterparts. Somewhat surprisingly, we generally find the highest migration wage differen-
28
29 tials for young *low-skilled* workers.²² Of special interest are the effects in RT1. Low-skilled migrants
30
31 to this region type exhibit a marked disadvantage with respect to the incumbent workforce if they be-
32
33 long to the intermediate or high-experience category. By contrast, all categories of highly-skilled mi-
34
35 grants immediately receive relative wage gains.²³ This result is at odds with the findings of GLAESER
36
37 and MARÈ (2001). Their general result that movers to metropolitan areas earn less than the stayers is
38
39 not supported by the evidence here.
40
41
42
43

44 **5.3 Comparing decomposition results at different levels of aggregation**

45
46
47 *Table 5* gives an overview for the decomposition results at different levels of aggregation. At the high-
48
49 est level we differentiate between region types only (model 1). We then add successively the dimen-
50
51 sions gender (model 2), skill (model 3) and experience (model 4). In model 5, the most comprehensive
52
53 model, all explanatory variables of the estimated equation are considered (region type/ skill/ gender/
54
55 experience and firm size). Note that for all models the rewards, characteristics and interaction effects
56
57 sum up to the total effect of 2.55.
58
59
60

+++++ Insert Table 5 about here +++++

1
2
3 In model 1 we observe that the rewards effect clearly dominates the characteristics effect. Including
4
5 the gender dimension in model 2 yields a positive characteristics effect (1.9 percent). This is due to the
6
7 over-representation of male workers in the group of movers. Taking the qualification of workers into
8
9 account (model 3) reinforces the characteristics effect since movers are more skilled on average than
10
11 immobile workers. So far, however, an important negative wage-determining factor in the typical
12
13 characteristics of movers –their low level of experience– has been neglected. Hence, model 3 over-
14
15 states the characteristics effect, which is mirrored by a strongly negative deviation in the rewards ef-
16
17 fect. As shown by model 4, controlling for experience reduces the characteristics effect considerably
18
19 (from 4.5 to 1.5 percent). Consideration of firm size adds a further negative component to the charac-
20
21 teristics effect (model 5). The reason for this lies in the fact that movers tend to work in smaller firms
22
23 than stayers. As can be concluded from the most comprehensive model, movers have less favourable
24
25 characteristics in total than stayers. Hence, the positive overall effect of mobility cannot be explained
26
27 by observed characteristics.
28
29
30
31
32
33

34 **6 Robustness checks**

35 36 37 38 **6.1 Unobserved heterogeneity**

39
40
41 An objection against the earnings-function approach used so far is that the results could possibly be
42
43 biased because of the neglect of unobserved heterogeneity. Mobile and immobile workers, for in-
44
45 stance, might differ in their career attitudes, working behaviour and other related factors that we can-
46
47 not directly observe. Hence, the positive earnings effects attributed to interregional mobility might
48
49 actually be due to this hidden information. A well-known approach for taking account of the time-
50
51 invariant part of unobserved heterogeneity is the fixed-effects model. Using data for 1996 and 1997
52
53 we ran a fixed-effects version of the earnings-function approach described in Section 4, where the time
54
55 invariant explanatory variables were dropped. According to the results shown in *table 6*, the wage
56
57 growth of movers exceeds that of observationally equivalent stayers by about 1.7 percentage points
58
59 with a t-statistic of 7.85. Hence the results of a wage advantage of movers over stayers survive the
60
consideration of time-invariant unobserved heterogeneity of workers.²⁴

1
2
3 +++++ Insert Table 6 about here +++++
4
5
6

7 **6.2 Propensity score matching**

8
9
10 To deal with the selectivity issue, one could alternatively use a matching approach.²⁵ The idea is that
11 the best estimate of the outcome variable for (untreated) individuals of a specific group is the outcome
12 of individuals with observationally equivalent characteristics in a reference group.
13

14
15 Let W_0 and W_1 denote two random variables for earnings of immobile or mobile workers, respectively,
16
17 and $D \in \{0,1\}$ be a dummy variable indicating whether a person belongs to the group of stayers
18
19 ($D = 0$) or the group of movers ($D = 1$). Furthermore, define X as a vector of characteristics. The
20
21 impact of migration on earnings for a mobile worker with (observable) characteristics X_i is the differ-
22
23 ence between the expected outcome of a mover with these characteristics, $E(W_{1i}|D_i = 1, X = X_i)$, and
24
25 the hypothetical situation that this individual would have expected had she or he stayed in the region
26
27 of origin $E(W_{0i}|D_i = 1, X = X_i)$. The problem is to find a suitable estimate for the latter expression
28
29 which is not observable. The basic idea of the potential outcome approach²⁶ is to replace the counter-
30
31 factual with the observed outcome of an individual (or individuals) from the control group with ideally
32
33 identical characteristics. With highly differentiated characteristics, however, finding exact matches is
34
35 hardly possible even in large data sets. To circumvent the curse of dimensionality the comparison is
36
37 based on similar rather than on identical individuals. As a measure of similarity we choose the propen-
38
39 sity score $\Pr(D_i|X = X_i)$ of a probit regression that describes the selection of individual i into the
40
41 treatment group.²⁷ There are several possibilities for constructing the counter-factual. A simple one is
42
43 the n -nearest neighbour method which uses the n observations in the control group most similar to an
44
45 individual in the “treatment group”, i.e. here, in the group of mobile workers. A more sophisticated
46
47 approach uses all observations of the control group but attaches weights to them which are lower the
48
49 more distant the observation is from the observation in the treatment group. These weights are calcu-
50
51 lated using a kernel estimate of the distribution.
52
53
54
55
56
57
58
59
60

1
2
3 In the probit regression we used all characteristics of workers as described in Section 4.²⁸ The selec-
4 tion into future movers and stayers is modelled using characteristics of 1996, i.e. the year before mi-
5 gration. For determining the wage effect of mobility one could either compare movers with stayers in
6 the region of destination or with stayers in the region of origin. For the first (second) alternative one
7 has to use 1997 (or 1996, respectively) characteristics in order to identify the corresponding matches
8 between movers and stayers. For the construction of the counter-factual we analysed the first nearest
9 neighbour approach and kernel matching as two extreme cases. It turns out, however, that both alterna-
10 tive matching methods produce similar results. The standard errors were generated by bootstrapping
11 (see, e.g. HECKMAN *et al.*, 1998).
12
13
14
15
16
17
18
19
20
21
22

23 In analogy to the fixed-effects method, the matching approach can also be based on wage growth rates
24 rather than on levels. In the empirical literature on programme evaluation (see, for example,
25 HECKMAN *et al.*, 1999; SMITH and TODD, 2005) it is assumed that the impact of unobservable
26 characteristics on the outcome is constant over time. Under this assumption, unobserved heterogeneity
27 is differenced out by using difference-in-differences matching. In our empirical application we consid-
28 ered this as a further alternative.
29
30
31
32
33
34
35

36 The results for the different variants of the matching approach are given in *table 7*. Comparing an un-
37 matched selection of movers and stayers in the year before migration confirms the result in *figure 2*,
38 showing that future movers have a wage disadvantage against future stayers. Matching reduces the
39 wage differential markedly in case of the nearest neighbour method (where it becomes statistically
40 insignificant) and less so in the case of kernel matching. This finding suggests that less favourable
41 characteristics of movers are at least partly responsible for lower wages in the year before moving.²⁹
42
43
44
45
46
47
48
49

50 +++++ Insert Table 7 about here +++++
51

52
53 In the year after migration the average treatment effect on the treated is about 2.6 percent for both
54 methods of constructing the counterfactual. This is in accordance with the 2.55 percent wage differen-
55 tial we found using the earnings function approach. Thus, the results of the matching procedure based
56 on (log) wage levels of movers and stayers support the findings documented in Section 5.
57
58
59
60

1
2
3 Applying difference-in-differences matching we find that the positive differential between the wage
4 growth rates of movers and stayers is only slightly reduced (from roughly 3 percent to 2.5 in the case
5 of nearest neighbour and 2.8 for kernel matching). We conclude that the positive effect of mobility on
6 wage growth cannot be explained by favourable unobserved characteristics of mobile workers at least
7 if these characteristics are not subject to a marked change over time.
8
9

10
11
12 The results of the different specifications of the matching approach using 1996 characteristics only are
13 contained in *table 8*. Here we additionally included 35 industry dummies and log wages in the year
14 before migration as further explanatory variables in the probit regression. The average treatment effect
15 of the treated turns out to be quite robust with respect to these changes.
16
17
18
19
20
21
22

23
24 +++++ Insert Table 8 about here +++++
25

26 As a further check of robustness we excluded data from metropolitan core cities and re-ran the differ-
27 ent estimation approaches. The effect of mobility exceeded those in *table 8* by about 0.5 percentage
28 points and also remained highly significant in this case.³⁰

34
35

36 **7 Conclusions**

37
38

39 The aim of this paper was to investigate the general and group-specific effects of interregional mobil-
40 ity on earnings. We find that in the year before workers migrate they have distinctly lower mean earn-
41 ings than their immobile colleagues. After migration, the average mobile worker typically catches up
42 with the average stayer in the region of destination or even experiences higher wages. This is the case
43 although movers tend to have less favourable characteristics than stayers. Hence, labour mobility leads
44 to a wage gain relative to stayers in the region of destination that cannot be attributed to observed
45 characteristics.
46
47
48
49
50
51
52
53

54 One should stress that the overall characteristics effect of movers is the result of strong opposing
55 forces. On the positive side, movers are typically more skilled. The fact that males are over-
56 represented in the group of movers also contributes to higher mean earnings. On the negative side,
57 mobile workers are younger, i.e. less experienced than their immobile counterparts. Compared to stay-
58
59
60

1
2
3 ers, a further structural disadvantage of movers is that they are more likely to work in smaller firms.
4
5 This aspect has been neglected in most of the literature concerning the migration wage differential.
6
7

8 It is interesting to compare our results with those of GLAESER and MARÈ (2001). These authors find
9
10 wage gains for movers to metropolitan areas because of a *wage level effect* due to the urban environ-
11
12 ment. Compared to the incumbent workforce in these areas, however, the earnings of movers fall be-
13
14 hind. Their explanation of this phenomenon is that the impact of favourable agglomeration forces be-
15
16 comes fully effective only after a certain period of time. Our results are at least partly at odds with
17
18 these findings. The evidence in the present paper indicates that earnings of several groups of movers
19
20 even surpass those of the incumbent workforce in core cities. All in all, our results support the hy-
21
22 pothesis that the *wage level effect* is not uniform across different groups of workers (as was implicitly
23
24 assumed in the approach chosen by GLAESER and MARÈ (2001)). Moreover, GLAESER and
25
26 MARÈ (2001) do not consider the effect of moving between non-metropolitan areas. Therefore, they
27
28 are not able to detect a positive effect of mobility independent of urban influences. Our empirical evi-
29
30 dence supports the hypothesis of a general effect. The estimation results presented indicate that the
31
32 post-migration wage differential is positive for most groups of workers *irrespective of the region of*
33
34 *destination*. Hence, it is at least questionable whether the wage level effect is fully caused by the urban
35
36 environment. Our findings corroborate the view that the gains from mobility mainly stem from the
37
38 actual decision to migrate.
39
40
41
42

43 Checking the robustness of the general results, we employ a fixed-effects model and several variants
44
45 of a matching approach. Irrespective of the method used, the positive effects of mobility are in the or-
46
47 der of magnitude of 2 to 3 percent and statistically highly significant. We conclude that the positive
48
49 impact of inter-regional mobility on earnings is not an artefact generated by differences in either ob-
50
51 served or unobserved characteristics of movers and stayers as long as the latter are confined to being
52
53 time-invariant.

improving the paper. We would also like to thank the participants of a session on regional labour markets at the annual meeting of the German Economic Association (Verein für Socialpolitik) and Alisher Aldashev for very helpful comments. We alone are responsible for any remaining errors. Financial support from the German Science Foundation (Deutsche Forschungsgemeinschaft, Projekt MO 523/ 3-2) is gratefully acknowledged.

Appendix

Description of the decomposition technique

Let the usual wage equation for mobile and immobile workers be given as $y = \mathbf{x}'\boldsymbol{\beta} + \epsilon$ and

$\mathbf{Y} = \mathbf{X}'\mathbf{B} + \mathbf{E}$ respectively. Then define $\Delta\hat{\boldsymbol{\beta}} := \hat{\boldsymbol{\beta}} - \hat{\mathbf{B}}$ and $\Delta\bar{\mathbf{x}} := \bar{\mathbf{x}} - \bar{\mathbf{X}}$, where the vectors $\bar{\mathbf{x}}$ and $\bar{\mathbf{X}}$ contain average values of the explanatory variables for movers and stayers respectively. The decomposition of the raw earnings differential $\bar{y} - \bar{Y}$ can be obtained as

$$\begin{aligned} \bar{y} - \bar{Y} &:= \bar{\mathbf{x}}\hat{\boldsymbol{\beta}} - \bar{\mathbf{X}}\hat{\mathbf{B}} \\ &= \underbrace{\bar{\mathbf{X}} \cdot \Delta\hat{\boldsymbol{\beta}}}_{\text{evaluation effect}} + \underbrace{\Delta\bar{\mathbf{x}} \cdot \hat{\mathbf{B}}}_{\text{characteristics effect}} + \underbrace{\Delta\bar{\mathbf{x}} \cdot \Delta\hat{\boldsymbol{\beta}}}_{\text{interaction effect}} \end{aligned} \quad (\text{A1})$$

Table 7:
Results from Nearest Neighbour and Kernel Matching

Level approach, outcome variable: wage				
	future movers	controls	ATET	z-value
<i>1996</i>				
Unmatched	149.86	152.26	-1.59	-
Nearest neighbour matching	149.86	150.00	-0.09	-0.09
Kernel matching	149.86	151.75	-1.25	-2.29*
	movers	controls	ATET	z-value
<i>1997</i>				
Unmatched	157.40	153.70	2.38	-
Nearest neighbour matching	157.40	153.28	2.65	2.51*
Kernel matching	157.40	153.33	2.62	3.52**
Difference-in-differences approach, outcome variable: wage growth (in %)				
	movers	controls	ATET	z-value
<i>1996/1997</i>				
Unmatched	4.96	2.03	2.93	-
Nearest neighbour matching	4.96	2.42	2.54	4.79**
Kernel matching	4.96	2.13	2.83	4.83**

Notes: **/* indicates statistical significance at the 1% level and 5% level. z-values are calculated by using a bootstrap method (300 replications for Nearest Neighbour Matching and 50 replications for Kernel Matching). The average treatment effect on the treated (ATET) is measured as log wage differential. Wages are calculated from log earnings. The probit regression is based on skill/ gender, experience, firm size and region type variables. In case of Kernel Matching the bandwidth is 0.06 (Stata standard). The presented results are robust with respect to the choice of the bandwidth.

Source: Authors' own calculations based on IAB-REG.

Table 8:
Results From Nearest Neighbour Matching Using 1996 Characteristics

Level approach, outcome variable: wage				
	movers	controls	ATET	z-value
	1997			
Nearest neighbour matching	157.40	153.77	2.33	2.14*
Difference-in-differences approach, outcome variable: wage growth (in %)				
	movers	controls	ATET	z-value
	1996/ 1997			
Nearest neighbour matching	4.91	2.63	2.28	4.61**

Notes: The probit regression is based on skill/ gender, experience, firm size and region type, log wages and industry variables in 1996. For further notes see *table 7*.

Table A1: Regional Classification Scheme Based on BBR-Classification

Structural region type	District type (BBR-Classification)	Region types (RT) used in the paper	Description of region type (BBR)
Regions with large agglomerations	BBR1	RT1	Core cities
	BBR2	RT1	Highly urbanized districts in regions with large agglomerations
	BBR3	RT2	Urbanized districts in regions with large agglomerations
	BBR4	RT2	Rural districts in regions with large agglomerations
Regions with features of conurbation	BBR5	RT3	Central cities in regions with intermediate agglomerations
	BBR 6	RT3	Urbanized districts in regions with intermediate agglomerations
	BBR 7	RT4	Rural districts in regions with intermediate agglomerations
Regions of rural character	BBR8	RT4	Urbanized districts in rural regions
	BBR9	RT4	Rural districts in rural regions

Endnotes

¹ The standard human capital model of migration predicts that workers migrate when the discounted value of real income available at a potential destination exceeds that at the origin by more than the costs of moving (SJAASTAD, 1962).

² TOPEL and WARD (1992) state that job search plays a crucial role for wage growth; they estimate that about 1/3 of overall wage growth in the first decade of working life can be attributed to job switching.

³ Some older studies dealing with the determinants affecting the probability of migration are DA VANZO (1978) and HERZOG and SCHLOTTMANN (1981) for the US. For a survey of other relevant studies see GREENWOOD (1975, 1985).

⁴ Spatial differences in productivity are crucial for explaining spatial wage differentials. Empirical studies in this context typically find a statistically significant positive relationship between density measures of economic activity and productivity (e.g. CICCONE and HALL, 1996; HARRIS and IOANNIDES, 2000). This supports the results of previous studies focusing on the positive effects of city population or industry employment on productivity (e.g. SVEIKAUSKAS, 1975; SEGAL, 1976; MOOMAW, 1981, 1985; HENDERSON, 1986).

⁵ In our data source gross daily earnings are calculated as average over the observed employment period for each person. The notions wages and earnings are used synonymously throughout this paper.

⁶ For an overview of region types according to this classification see table A1 in the Appendix.

⁷ See, for instance, KEMPER (2006) for an exploration of migration patterns in Western and Eastern Germany.

⁸ This definition does not differentiate between migration and commuting. In analogy to the distinction made by ELIASSON et al. (2003, p.831), the definition of movers in our paper includes the following categories: (i) workers who change their region type of residence and the region type of work place; (ii) workers who do not change their place of residence, but start commuting to a different type of region; (iii) commuters who do not change their place of residence, but change the region type where the work place is located. Because our definition of mobility is based on region *type*, our concept of mobility is predominantly related to the first category. Note that adjacent regions are in many cases of the same type.

⁹ The described differences are robust within the sample period 1990 to 1997.

¹⁰ The measure of concentration is calculated as: $100 \times \frac{\text{share of movers of this category in total movers}}{\text{share of movers and stayers of this category in total workers}}$.

¹¹ HUNT (2004) states that those results are strongly influenced by a special group of movers. Workers who migrate from one state to another without changing the employer are more highly educated than stayers.

¹² Here and in the following potential experience in years is measured as age minus average duration of education minus 6. For low-skilled workers without an upper secondary education we assume 10 years as the average educational period, for low-skilled workers with an upper secondary education 13 years, for skilled workers 12.5 and 15 years respectively, for highly-skilled workers holding a polytechnic type of degree 16 years and for highly-skilled alumni of a university 18 years.

¹³ The potential work experience is categorized as follows: low experience: 0 - 9 years; medium experience: 10 - 19 years; high experience: 20 or more years. In order to avoid problems with cell sizes being too small, we aggregated the BBR-region types and firm size categories (see tables A1 and A2 in the Appendix).

¹⁴ For some years in the sample the share of movers is even under-represented in this region type. In 1994 and 1992, for example, the share of mobile workers in RT1 was just 49%, while more than 50% of all stayers worked in this region type.

¹⁵ See MINCER (1974).

¹⁶ Here we included a category “firm size missing”.

¹⁷ All workers except for low-skilled male and female workers are considered to be qualified. All interactions are defined for the linear and quadratic experience variable.

¹⁸ We calculated corresponding estimates for all successive pairs of years in our sample. It turns out that the findings are sufficiently robust over time. In order to save space, we present the results in the following for the most recent years only. The results for other pairs of years are available from the authors on request.

¹⁹ The differential of low-skilled male workers relative to the average in the economy, for example, is obtained as $\hat{a}_{1,1} = -\hat{a}_{n=2}^6 w_n \hat{a}_{1,n}$, where w_n denotes the share of category n workers in total employment. The skill differentials of workers in categories $n = (2, 3, \dots, 6)$ are recalculated according to the formula $\hat{a}_{1,n}^0 = \hat{a}_{1,1} + \hat{a}_{1,n}$. A corresponding procedure was applied to the coefficients of firm size and region type category variables as well.

²⁰ An explanation of the BLINDER- OAXACA (1973) type decomposition technique is given in the Appendix.

²¹ The differentiation by gender and firm size is neglected to keep the table readable.

²² This is in accordance with the findings of YANKOW (2003) for the US. He points to the fact that this group of migrants searches for immediate wage gains, while highly educated young migrants invest in their human capital.

²³ Note that the overall differential between highly-skilled movers and stayers in RT1 is negative, while the differential is positive for all experience groups. This is due to the fact that experience (or age) of movers and stayers differs markedly. Typically the group of young or not experienced workers is clearly over-represented in the group of movers. The fact that this group earns significantly less than the high-experience group explains the negative difference (−2.53) for the category RT1/ highly-skilled.

²⁴ A further objection against our method is that only workers are considered who are employed before and after moving. If participation and employment rates vary systematically over types of regions, our results cannot be generalized to the whole working age population. PEKKALA and TERVO (2002) present an approach which explicitly takes account of this selectivity issue. Their approach requires instruments which are not available in our data set. However, we checked the existence of a possible influence of the type of region on employment and participation rates. A scatter plot between population density and employment or participation rates across 439 German NUTS 3 regions shows no significant relationship. Therefore, we feel confident that this possible source of bias in our results is not substantial.

²⁵ For an overview of recent developments of this approach see COBB-CLARK and CROSSLEY (2003) or SMITH and TODD (2005).

²⁶ See ROY (1951) and RUBIN (1974).

²⁷ The basic idea goes back to the seminal contribution of ROSENBAUM and RUBIN (1983).

²⁸ The results of the probit model are not documented in the paper, but are available on request from the authors. For the calculation of the matching model we used the Psmatch2 Stata module (Version 3.0.0) by LEUVEN and SIANESI (2003).

²⁹ We conducted the usual diagnostics on the success of matching without finding any clues for questioning the results. The common support assumption is fulfilled in our case. After matching, the differences in characteristics between movers and controls are statistically insignificant.

³⁰ The results are available from the authors on request.
