Early Labour-Market Experiences of Second-Generation Immigrants in Sweden

Abstract

This paper investigates second generation immigrant's early labour-market performances in Sweden. To study their labour-market success we estimate dynamic transition rate models -Cox type proportional hazards, in a competing risk framework using register based panel-data set. Our results reveal that parental resources affect not only second-generation immigrants' continuing education but also their later labour-market success. The study verifies that finding a job is difficult for second-generation immigrants and the significant unobserved-heterogeneity parameter estimate may indicate discrimination. As a whole, second-generation immigrants have worse labour-market performances compared to their native-born counterparts.

Keywords: Second-generation immigrants, labour-market experiences, duration-models, competing-risks, unobserved heterogeneity.

J.E.L. Classification: C23, C24, C41.

1 Introduction

The purpose of this paper is to analyse the early labour-market experiences of second-generation immigrants in Sweden. One might think that “second-generation” immigrants, born in the country new to immigrant parents, would be better off than their parents in terms of economic and social integration since they go to school in the new country, and thus have better opportunities to learn the language, make friends with the native population, and develop country-specific human capital. But what about the empirical facts? What kind of early labour-market experiences have second-generation immigrants had after finishing compulsory education? This paper attempts to find answers to these questions.

Although there is a vast literature about first generation immigrant’s economic integration, there are few studies about second-generation immigrants, either in the United States (Chiswick, 1977; Carliner, 1980; Borjas, 1992, 1993, 1994; Card *et al.*, 1998) or in Europe (Gang and Zimmerman, 2000; Nielsen *et al.*, 2001; Riphahn, 2001; Van Ours and Veeneman, 2001, 2002; Ekberg and Rooth, 2002). A problem common to these studies is the type of data used: most of these studies are based on cross-sectional data sets. In general, cross-section studies do not permit to making strong causal interpretations. On the contrary, Lam (1996)

1
2
3
4 found, for instance, that the cross-sectional estimates of the growth in
5 earnings of immigrants in the United States were underestimated for
6 these groups of immigrants when the results of cross-sectional estimates
7 were compared with the results of longitudinal data.
8
9
10
11
12
13

14 In this paper, we aim to improve the analysis of second-generation
15 immigrants' economic integration in three aspects: data set, models and
16 results. The contribution of this paper is therefore threefold. The first
17 contribution is methodological and related to the data set we use. Lon-
18 gitudinal research has certain advantages, such as measuring change and
19 establishing temporal order, but there are offsetting difficulties since it
20 requires more advanced techniques. The data set, which we use in this
21 study is a longitudinal one for the period 1991-2000. The annual ob-
22 servations are based on a Swedish register data set called Longitudinal
23 Individual Data (LINDA) and it is rich with the socioeconomic variables.
24 We draw a statistical twin sample for native-borns, which is also ran-
25 domly chosen and helps us to make reliable comparisons. It is different
26 from other data sets that are used in the analysis of second-generation
27 studies in many aspects. The early experiences of new entrants into
28 the labour-market may help determine developments later in their life.
29 Those who are 16-25 years old may encounter many important changes,
30 such as completing their education, getting their first job, building a
31 family and becoming a parent. All of these factors will affect their later
32 labour-market behaviour and success, such as time spent in employment,

1
2
3
4 and returns from human-capital investment such as wages. Besides, the
5
6
7 heterogenous feature of the second-generation immigrants are taken into
8
9
10 account by grouping them into similar geographical units. The second-
11
12 generation immigrants are all from the same age cohorts. They are 16/17
13
14 in 1991 and 25/26 in 2000. This prevents us from average age differences
15
16 across ethnic groups which can affect the results.
17
18

19
20 The second contribution of this paper is also methodological and re-
21
22 lated to the models we estimate, which are dynamic and control unob-
23
24 served heterogeneity. We estimate four different types of transitions mod-
25
26 els into the labour-market: The first two are from compulsory and post-
27
28 compulsory education to various competing states; the last two are from
29
30 non-employment to work after compulsory or post-compulsory educa-
31
32 tion. The first transition is modelled by fitting a multinomial-logit model
33
34 since the waiting-time after compulsory education is the same for all in-
35
36 dividuals and there is no time-dependency. The transition from post-
37
38 compulsory education to work, non-employment or the military is mod-
39
40 elled in a competing-risks hazard-framework by using semi-parametric
41
42 Cox and parametric duration-dependence distributions. We also look to
43
44 the transitions to work after non-employment after compulsory and post-
45
46 compulsory education. Based on the results of an information-matrix
47
48 test, we fit hazard-models to both of the transitions —transition from
49
50 post-compulsory education to various states and transition from non-
51
52 employment after post compulsory education to work— taking into ac-

count inter-individual heterogeneity.

The third contribution of this paper is a substantive one and related to the evidences we find for the debate of immigrant's economic integration, which do not support a quick economic integration of immigrants, the so called "melting pot" hypothesis. Our results reveal that parental resources affect not only the second-generation immigrants' continuing education but also their later labour-market success. For all young people, regardless of their ethnic background, parental capital in the form of educational attainment, occupation and income are vital. Ethnic capital and neighbouring characteristics such as other inter-generational transmission-channels are also important. The study verifies that finding a job is difficult for second-generation immigrants, especially for those coming from Africa, Latin America and Middle East. The significance of an unobserved-heterogeneity parameter may indicate discrimination. As a whole, second-generation immigrants have worse labour-market performances than their first-generation counterparts and weaker chances for an economic catch-up and thus slow economic integration with persistent earning-differentials from their native-born counterparts. The conclusions drawn using such dynamic models, estimated using the Swedish panel data set are giving much more convincing support to Borjas' North-American results of a long integration process of immigrants, and imply some necessary changes in the current economic policies for second-generation immigrants.

The evidences found in this study therefore raise some policy implications. First, an increase in the economic income status and an improvement of the labour market attachment of the low-income families will also lead to a progress in their children's entry into labour market. We therefore suggest policies to achieve a more equal income distribution in the society in the long run.

Second, the low probabilities of finding a job for second-generation immigrants, especially for those coming from Africa, Latin America and Middle East require some origin country-specific arrangements. We thus recommend policies, such as giving specific information to these groups or arranging special campaigns for them in the short run.

Third, discrimination of immigrants in the labour market makes necessary some anti-discrimination measures in the society, in general.

Next section reviews previous research about second-generation immigrants. Section 3 presents the theoretical issues while Section 4 describes the data and discusses sample-selection issues. Section 5 analyses the modelling issues. Section 6 presents the results and finally the last section offers a conclusion.

2 Previous research about second-generation immigrants

2.1 Studies in the United States

Europe and the United States, and especially Sweden and United States, differ in many respects, including differences in social policies and provisions of the welfare state. An important goal of Swedish immigrant policy has been to assure equal opportunities of immigrants, who should have the same employment and income earnings, although this has not always worked out in practice. Even post-compulsory education is tuition-free for all in Sweden and there is a fairly generous transfer system, including low-cost medical care. Nevertheless, both US studies and those from other European countries may be relevant to Swedish experience. Using US census-data to analyse contemporary immigrant-flows, Chiswick (1977), Carliner (1980) and Borjas (1992, 1993 and 1994) come to different conclusions about the experience of the sons of immigrants in the US labour market. Using data from the 1/1000 sample of the 1970 Census of Population, Chiswick found that sons of immigrants had a 5 per cent earnings-advantage over native-born white male Americans. Both Chiswick and Carliner concluded that characteristics associated with positive selection in the immigrant-population had been transmitted to their children. Analyzing the inter-generational mobility experienced by immigrants in the context of economic model of immigration, Borjas (1993)

1
2
3
4 questioned Chiswick's and Carliner's results, since their studies were
5
6 based on cross-sectional data. Borjas examined the earnings of immi-
7
8 grants and second-generation immigrants across decennial censuses from
9
10 1940 to 1970. Assuming that first-generation immigrants in the 1940 cen-
11
12 sus were the parents of second-generation immigrants in the 1970 census,
13
14 he found that, although there was some regression toward the mean, the
15
16 average earnings of the second-generation of any given ethnic group were
17
18 strongly influenced by the earnings of the corresponding first-generation
19
20 group. He postulated that the immigrant characteristics in the source
21
22 countries which determine migrant-selection had introduced differentials
23
24 in skills between ethnic groups which resulted in persistent earnings-
25
26 differentials. Field-Hendrey and Balkan (1991) investigated the earnings
27
28 and assimilation of female immigrants to the US, using 1970 and 1980
29
30 data. They found that, taken as a group, female immigrants with sim-
31
32 ilar characteristics to natives had initially lower earnings but did catch
33
34 up within about ten years. Later on, Card, DiNardo and Estes (1998)
35
36 found that, despite the fact that an increasing fraction of today's second-
37
38 generation immigrants were the grandchildren of the formerly lowest-paid
39
40 immigrant groups, they now tended to have higher wages than long-time
41
42 natives.

2.2 Studies in Europe

2.2.1 Educational attainment

In Europe, most of the research about second-generation immigrants has been done in Germany, the Netherlands, Denmark, and Sweden. Since understanding the economic integration of ethnic communities requires understanding of the human capital process, educational attainment has been one of the main research topics.

Gang and Zimmerman (2000), using information for 1984 from the German Socioeconomic Panel, explored three aspects of educational attainment: total years of education, schooling-level, and vocational training. Their sample consisted of 4678 individuals, 17-38 years old, 3895 of whom were Germans while 783 were second-generation immigrants. They found that parents' education had no effect on the educational attainment of their children, but that ethnicity mattered. They concluded that the effects of the parents' education had been completely depreciated, and that the inter-generational transfer of human capital disappeared with the shock of immigration.

Riphahn (2001), using five pooled microcensuses (a one percent random sample of the population) from 1989, 1991, 1993, 1995 and 1996, estimated completed degrees and school-attendance of second-generation immigrants in Germany. The sample consisted of 55,570 natives and 3,627 second-generation immigrants. By focusing on the development over time using an ordered-probit model, she found that second-generation

60

immigrants did not assimilate to the native education-level and that the attainment-lag did not diminish over time. She interpreted this by pointing to the changing country of origin of second-generation immigrants.

Van Ours and Veeneman (2001) explored the extent to which differences in educational attainment between second-generation immigrants and natives exist in the Netherlands. Using a 1998 nationwide survey where the second-generation immigrants consisted of Turks, Moroccans, Surinamese, and Antilleans, they analysed the probabilities of continuing education and of the level of education attained, with binary-probit and ordered-probit models, respectively. Their main conclusion was that, controlling for parental education-level, differences between second-generation immigrants and natives largely vanished.

Nielsen et.al. (2001), using Danish panel-data originating from administrative registers covering the period 1985-1997, focused on the probability of obtaining a “qualifying education”, defined as education lasting at least 18 months beyond the compulsory level. Their results indicated that, for males the number of years since the parents immigrated to Denmark had a statistically significant positive effect, whereas for females the parents’ income was an important factor affecting them positively. The education of parents was found to be statistically significant only for ethnic Danes, while having parents with several years of labour-market experience had a statistically significantly positive effect for all groups.

Until the early 1970s, immigration to Sweden was mostly labour-force

1
2
3
4 migration from other European countries. But since then, political up-
5
6 heavals elsewhere and immigration policy have caused the character of
7
8 immigration to change. The number of refugees and tied movers has
9
10 increased, regardless of the state of the labour market. Parallel with
11
12 deterioration in the labour-market during the 1970s, unemployment in-
13
14 creased in Sweden among immigrants. During the 1980s the employment-
15
16 intensity among immigrants continued to fall, despite improvements in
17
18 the labour-market from the mid-1980s onwards, see Ohlsson (1975), Ek-
19
20 berg and Gustafsson, (1995). Immigration reached its highest levels
21
22 during the extreme boom of the late 1980s, but with the recession at
23
24 the beginning of the 1990s, unemployment among immigrants increased
25
26 further. Nevertheless, immigrants have stayed in Sweden, built fami-
27
28 lies, and raised children conventionally called “second-generation immi-
29
30 grants”. Österberg (2000), using the Swedish Income Panel, where 98
31
32 percent of the second-generation immigrants had European background,
33
34 analysed level of educational attainment using an ordered probit model.
35
36 She found that the parents’ education had a positive effect on the child’s
37
38 educational level which decreased the negative effect from belonging to
39
40 certain ethnic groups.

45
46
47
48
49
50

51 52 53 **2.2.2 Early labour-market experiences**

54
55
56 Van Ours and Veeneman (2002) using the same Netherlands data as be-
57
58 fore, investigated the early-labour market experiences of second-generation
59
60 immigrants. Using a simple probit-model to model the probability that

1
2
3
4 individuals had a job while still at school, they found that it was an age-
5
6 related phenomenon, rather than depending on the level of education
7
8 or on “neighborhood” characteristics. They also focused on the prob-
9
10 ability of having a job conditional on being out of school. The results
11
12 of their bivariate-probit model pointed to the importance of the level
13
14 of education for females in finding a job. For both males and females,
15
16 Turkish and Moroccans had greater difficulty in finding a job. Again us-
17
18 ing a bivariate-probit model, they found that the probability of having
19
20 a steady job increased with work experience, while for males education
21
22 mattered. Turkish and Surinamese females were less likely to hold a
23
24 steady job. Regarding the amount of hourly wages, taking possible se-
25
26 lectivity into account, they found that education had a statistically sig-
27
28 nificant effect for males, while ethnicity did not matter.
29
30
31
32
33
34
35

36
37 Nielsen et.al. (2001), focused on three aspects of the early-labour
38
39 market experiences of second-generation immigrants in Denmark: time
40
41 from leaving school until the first ordinary job; duration of the first un-
42
43 employment spell; and hourly wages. In terms of data-structure and
44
45 estimation-methods, this study was the closest to our work in this paper.
46
47
48 Using a proportional-hazards model with a piecewise constant baseline-
49
50 hazard for the waiting time, they found that parental capital had strong
51
52 effects on entry into the labour market for females, whereas ethnic cap-
53
54 ital and “neighborhood” variables were also important for males. The
55
56 education of parents had a negative effect, which they interpreted as a
57

perverse effect on the probability of taking a first job.

Büchel and Frick (2003) use a panel data from the European Community Household Panel and study and expect that a successful and integrative immigration policy should result in a non-significant differential between the economics performance of immigrants and that of the indigenous population. Their results show, however, that this “ideal” is not attained in all of the analysed countries, particularly in Germany and Denmark, where the economic performance of immigrants measured in terms of the country-specific pre-government position and change in relative income position is much lower than that of the indigenous population.

Ekberg (1997), conducted the first study about second-generation immigrants in Sweden. His descriptive analyses, based on 1994 labour-market data from Statistics Sweden, showed that most were born before 1970, of European origin, had integrated well into the labour-market with hardly any difference between them and the native Swedes. The situation was completely different for those born after 1970, for whom there were also differences between ethnic groups. Månsson and Ekberg (2000), found a similar result.

Using Swedish survey data from 1988, Schröder and Wilhelmsson (1998) analysed labour-market position of second-generation immigrants seven years after graduation, where labour market position was categorized as; working; unemployed; studying; out of labour force; or other.

1
2
3
4 Estimation results based on a multinomial-logit model indicated that
5
6
7 second-generation immigrants, especially those coming from Asia, Africa,
8
9 or Latin America, had a disadvantage in the labour-market. Second-
10
11 generation immigrants who migrated after compulsory school age had a
12
13 higher probability of being unemployed compared to those who immi-
14
15 grated earlier or were born in Sweden, and the differences persisted even
16
17
18 other variables such as language proficiency and other Sweden-specific
19
20 human capital were controlled.
21
22

23
24 Ekberg and Rooth (2002), divided 1998 data from National Labour
25
26 Market Board (AMS) and Statistics Sweden into two subsets and focused
27
28 on the probability of being unemployed for 25-40 year-old individuals
29
30 who were part of the labour-force, according their earning levels. Probit-
31
32 regression for the first outcome (unemployment) and OLS for the second,
33
34 indicated that the outcomes differed greatly between different groups of
35
36 second- generation immigrants, and in comparison to native born Swedes.
37
38
39 The pattern was similar to that in the parent generation. The outcome
40
41 was more favorable if one parent was born in Sweden.
42
43
44
45

46
47 Second-generation immigrants had not only higher probabilities of be-
48
49 ing unemployed compared to those who immigrated earlier or were born
50
51 in Sweden, but also had higher risks of being hospitalised for mental dis-
52
53 orders. Leão et.al. (2005) studied this incidence for second-generation
54
55 immigrants in Sweden and found that second-generation adult immi-
56
57 grants had a higher risk of being hospitalised for mental disorders than
58
59
60

1
2
3
4 the Swedish majority population after adjustment for socio-economic sta-
5
6
7 tus. This risk was also higher for second-generation refugees than for the
8
9
10 Swedish majority population but only for psychotic disorders.

11 12 13 14 **3 Determinants of early labour-market ex-** 15 16 17 18 **periences and related hypotheses** 19

20
21
22 It is not clear what hypotheses to use for the early labour-market ex-
23
24 periences of second-generation immigrants. Early works point to the
25
26 inter-generational transmission process, whereby the weak labour-market
27
28 position of first-generation immigrants would be transmitted to their chil-
29
30 dren through various channels: parental capital, or direct effects from the
31
32 parents; ethnic capital; and neighborhood effects. This was also the main
33
34 point of Coleman (1988) where he asserted that both social capital in the
35
36 family and social capital in the community play roles in the creation of
37
38 human capital in the rising generation.
39
40
41
42
43

44
45 However, one has to be careful in defining these entities. For exam-
46
47 ple, family background also includes financial capital and human capital,
48
49 approximately measured by the parents' education which contributes to
50
51 the cognitive environment of the child. Family social capital is different
52
53 from either of these. Family human capital may be irrelevant if it is not
54
55 complemented by social capital embodied in family relations, which in
56
57 turn can depend on the number of parents present, the number of siblings
58
59
60

1
2
3
4
5 in the family, parental time devoted to the children, etc.
6

7 In immigration literature, the seminal work on the second-generation
8 immigrants was carried out by Borjas (1992, 1993 and 1994). Borjas
9 (1995) extended the notion of social capital to include ethnic capital and
10 its interaction with neighbourhood effects. Ethnic capital may include
11 linguistic skills and external effects from the average human capital of
12 the ethnic group, as a whole while neighbourhood effects include the
13 negative impact on youths growing up in poor neighbourhoods. Accord-
14 ing to Borjas, residential segregation and ethnic external effects may be
15 linked since ethnic capital includes the socioeconomic background of the
16 neighborhood.

32 In our data parental characteristics are rich allowing us to disag-
33 gregate the sources of family income, such as father's labour-income,
34 mother's labour-income, family asset-income and family welfare-income.
35 Such an approach, used also by Hill and Duncan (1987), enabled us to
36 test various human capital hypotheses such as the role-model hypothesis
37 and the welfare-dependency hypothesis, which have implications for the
38 success and social integration of the child. To test neighbourhood ef-
39 fect, we constructed a variable called "ethnic concentration", see Nielsen
40 *et.al.* (2001) and Cardak and McDonald (2004), which is the percentage
41 of first-generation immigrants in the municipality.

4 The data and sample-selection

The data-set used in this study is the 1991-2000 panel of the register-based Longitudinal Individual Data-set (LINDA), a database of about 300,000 individuals and their household members. The core of the data is the annually-available Income Registers and Population Censuses. The database contains individuals' socioeconomic characteristics such as education related variables and labour market related variables, such as employment-status, labour-income, etc. Family members are only included in the sample as long as they stayed in the family.

Our sample, following Kossoudji, (1989), consisted of second-generation immigrants who were either born in Sweden, or immigrated before six years of age and who were 16-17 year old in 1991. We included children who migrated before the age of six, since they started school with native Swedes and had the opportunity to thoroughly learn the language of the migrated country at a very early period of their life cycle. In other words, they have access to the migration country's specific human capital. In 1991, there were 1106 second-generation immigrants and these individuals can be traced until they reach age 25-26 in 2000. The geographical origin of second-generation immigrants was determined from the father's country of birth (or if only the mother was foreign-born, it was determined from hers). A control-group of 1106 same-age native Swedes (16-17 years old in 1991, born in Sweden with both Swedish parents) was matched by county of residence were also traced until they

1
2
3
4 reach age 25-26 by 2000.
5
6

7 We have analysed four sets of labour-market experiences. The first
8
9 was the transition from compulsory school to various states: continuing
10 their education, finding a job, or non-employment. Among the 2212 indi-
11
12 viduals in both groups, 1941 continued their education while 162 found a
13
14 job and 109 were non-employed during the first year after compulsory ed-
15
16 ucation. None of the 109 individuals returned to school during the follow-
17
18 ing 10 years of the study period while the overwhelming majority of the
19
20 162 individuals who found a job continued to work. Next we analysed the
21
22 transition from continuing education to work, non-employment, or the
23
24 military. Of the 1941 native Swedes and second-generation immigrants
25
26 who initially continued their education, 637 transited to work, 657 to non
27
28 employment, while some 262 went to military and the rest continued in
29
30 school. Finally we looked at transitions from non-employment to work
31
32 or the military, either after compulsory education or after continuing
33
34 education.
35
36
37
38
39
40
41
42
43

44 A list of the variables and their sample characteristics are given in
45
46 Table 1. Just over a half of the 1106 second-generation immigrants were
47
48 males, compared with just under a half of the native Swedes. About
49
50 only a third of the second-generation immigrants had been born outside
51
52 Sweden. Three quarters lived in two-parent families, essentially the same
53
54 as native Swedes. The number of siblings was slightly higher for the
55
56 immigrants. The average age of the “head of household” (the father if
57
58
59
60

1
2
3
4 two parents were present) was almost the same for second-generation
5
6 immigrants and for native Swedes (about 46).
7
8
9

10
11 [Table 1 about here]
12
13
14

15 We classified parent's education according to the highest level at-
16 tained by at least one parent: compulsory level; high-school level; or
17 university degree. Considerably more immigrant parents had completed
18 ninth grade only (27.7 percent) than native Swedish parents (15.5 per-
19 cent). On the other hand, considerably more native Swedish parents
20 (37.1 percent) than immigrant parents (28.8 percent) had a college or
21 university degree. The percentages who had completed high-school were
22 more similar though slightly higher for native Swedes.
23
24
25
26
27
28
29
30
31
32
33
34

35 Nearly half of the second-generation immigrants were of Nordic ori-
36 gin, most of them Finnish. The rest can be classified in six groups coming
37 from industrialized western countries, including USA, Australia, Canada
38 and the EU; Eastern Europe; Middle-East; Asia; Africa; and Latin Amer-
39 ica.
40
41
42
43
44
45
46
47

48 The ethnic concentration, was only slightly higher for second-generation
49 immigrants than for native Swedes.
50
51

52 Native Swedes had only slightly more total parental income than did
53 second generation immigrants. Father's labour income, mother's labour
54 income, and asset income were all substantially higher for native Swedes,
55 whereas parents' welfare income was somewhat higher for the immigrants,
56
57
58
59
60

though not enough to make up the difference.

5 Statistical modelling

Transiting from compulsory education to various states is analyzed using multinomial logit regression —since there was no time-dependency— the later transitions from continuing education or from initial non-employment after compulsory-education to various states are modeled in a competing-risks framework, and transition from non-employment after post-compulsory education to work is modeled in a single-destination framework. This means not only that we analyzed the duration of the non-occurrence of the event of interest —except transitions from compulsory education— but we also distinguished between different types of transitions. We assumed a priori that the occurrence of each type of transition had a different causal structure. The same covariates might be relevant but each transition could have an independent set of parameters, see Kalbfleisch and Prentice (1980 and 2002).

When time T is continuous and measured precisely so that there are no ties, such continuous time survival procedure could be adopted: let x be a vector of covariates. In a competing-risks framework, a cause-specific or type-specific model can be represented by

$$h_j(t; \mathbf{x}) = \lim_{dt \rightarrow 0} dt^{-1} P(t \leq T < t + dt, \quad J = j \mid T \geq t, \mathbf{x}) \quad (1)$$

where $j = 1, \dots, m$ and $t > 0$; $h_j(t; \mathbf{x})$ denotes the instantaneous risk of experiencing a transition of type j in the time interval $(t \leq T < t + dt)$ given that no transition occurred before $T = t$. The overall hazard-rate can be obtained by summing the transition specific hazard rates, that is,

$$h(t; \mathbf{x}) = \sum_{j=1}^m h_j(t; \mathbf{x}) \quad (2)$$

The overall survivor function is

$$S(t; \mathbf{x}) = P(T > t | \mathbf{x}) = \exp \left(- \int_0^t h(u; \mathbf{x}) du \right)$$

if we substitute in the transition specific hazard rates then we obtain

$$\begin{aligned} S(t; \mathbf{x}) &= \exp \left(- \int_0^t \sum_{j=1}^m h_j(u; \mathbf{x}) du \right) \\ &= \prod_{j=1}^m \exp \left(- \int_0^t h_j(u; \mathbf{x}) du \right) \end{aligned} \quad (3)$$

The density-function for the time until a type j transition is then

$$\begin{aligned} f_j(t; \mathbf{x}) &= \lim_{dt \rightarrow 0} dt^{-1} P(t \leq T < t + dt, J = j | \mathbf{x}) \\ &= h_j(t; \mathbf{x}) S(t; \mathbf{x}) \end{aligned} \quad (4)$$

It must be noted, however, that $f_j(t; \mathbf{x})$ is not the density-function of the duration-time. In particular

$$\int_0^{\infty} f_j(t; \mathbf{x}) dt = P(J = j | \mathbf{x}) = \pi_j(\mathbf{x}) \quad (5)$$

where $\pi_j(\mathbf{x})$ is the probability of transition into the j th state $j = 1, \dots, m$, given the covariate-vector \mathbf{x} , with the relationship

$$\sum_{j=1}^m \pi_j(\mathbf{x}) = 1 \quad (6)$$

If $t_{j1} < t_{j2} < \dots < t_{jn_j}$ represents the n_j uncensored durations until the transition j , then the likelihood-function may be rewritten as

$$L = \prod_{j=1}^m \prod_{k=1}^{n_j} h_j(t_{jk}; \mathbf{x}_{jk}) \prod_{i=1}^n S_j(t_i; \mathbf{x}_i) \quad (7)$$

where \mathbf{x}_{jk} is the covariate of an individual with the observed non-censored duration t_{jk} and

$$S_j(t_i; \mathbf{x}_i) = \exp\left(-\int_0^{t_i} h_j(u; \mathbf{x}_i) du\right) \quad (8)$$

The likelihood-function may be divided into the product

$$L = \prod_{j=1}^m L_j \quad \text{with} \quad L_j = \prod_{k=1}^{n_j} h_j(t_{jk}; \mathbf{x}_{jk}) \prod_{i=1}^n S_j(t_i; \mathbf{x}_i) \quad (9)$$

The L_j -factors may be further rearranged as

$$L_j = \prod_{i=1}^n [h_j(t_{jk}; \mathbf{x}_{jk})]^{\delta_{ij}} S_j(t_i; \mathbf{x}_i) \quad (10)$$

$$\text{with } \delta_{ij} = \begin{cases} 1 & \text{if for individual } i \text{ a transition to state } j \text{ occurs at time } t_i \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

The log-likelihood function $\ln L = \sum_{j=1}^m \ln L_j$ can be maximised separately for each transition type $j = 1, \dots, m$, given that the transition-specific hazard rates $h_j(t | \mathbf{x})$ are dependent upon the parameter-vector θ_j , where the θ 's have no common components. In particular, a parametric model $h_j(t; \mathbf{x}, \theta_j)$ can be specified for the type-specific hazards (see, Cox and Oakes, 1984).

For the transitions from continuing education to various states, as well as later transitions from non-employment after compulsory or post-compulsory education, we first plotted the smoothed non-parametric hazard functions against time and the hazard functions displayed non-monotonic curves. The log-logistic model was ideal in catching the turning-points in these cases. We then fitted log-logistic model¹ in the competing-risks framework discussed above, since in the case fitting a proper parametric distribution function one can obtain more efficient estimates than estimates of a semi-parametric model. In addition, we also fitted Cox proportional-hazards model.² Since Cox's method does not require some particular probability distribution to represent survival times,

58
59
60

it is considerably more robust. It can also accommodate both discrete and continuous measurements of transition times. The cause-specific hazard functions mentioned above, can be modeled by using Cox model in the following way:

$$h_j[t; \mathbf{x}_i] = h_{0j}(t) \exp[\mathbf{x}'_i \beta_j], \quad j = 1, \dots, m, \quad (12)$$

where \mathbf{x}_i is a vector of covariates, h_{0j} and β_j are the baseline hazards and the regression coefficients respectively which vary arbitrarily over the m transition types. As before, let $t_{j1} < t_{j2} < \dots < t_{jn_j}$ represent the n_j uncensored durations until the transition j , $j = 1, \dots, m$. The corresponding partial likelihood is

$$L(\beta_1, \dots, \beta_m) = \prod_{j=1}^m \prod_{i=1}^{k_j} \frac{\exp[x_i \beta_j]}{\sum_{l \in R(t_{ji})} \exp[\mathbf{x}'_l \beta_j]} \quad (13)$$

the arbitrary baseline hazard function has been eliminated and the resulting likelihood can be used for inferences about β_j 's.

The modelling issues above rely on the implicit assumption that the exogenous variables were measured without any error and that there were not any omitted variables in the model. In other terms, there was an implicit assumption that the error term in the model had white noise characteristics. If we have any omitted variable in the model the omission of such an effect can introduce important biases on the estimates of the parameters of interest (Gourieroux, 1989). The results based on

1
2
3
4
5 Information Matrix Test detected such unobserved heterogeneity in the
6
7 case of transitions from continuing education to various states, as well
8
9 as transition from non-employment after continuing education to work
10
11 (see Appendix A). As a result, we introduced a gamma type unobserved
12
13 heterogeneity term to the parametric and semi-parametric specifications
14
15 mentioned above, which is the survival-data analog to regression mod-
16
17 els with random effects. Such an unobserved heterogeneity is a latent
18
19 random effect that enters multiplicatively on the hazard function.

6 Results

6.1 Transitions from compulsory education

After the completion of compulsory education at ages 16-17, everyone in the sample either continued their education, went to work, or transitioned to non-employment. Table 2 shows the estimated parameters from the multinomial-logit regression for those who transitioned to work, continued to higher education or transitioned to non-employment.

Having at least one Swedish parent made the odds of continuing education versus working 1.6 ($\approx \exp(0.496)$, looking at the first column) times higher, and the odds of continuing education versus being in a non-employed state 1.8 ($\approx \exp(0.563)$),⁴ looking at the second column) times higher. The parameter of coming from a two-parent family is also statistically significant and made the odds of continuing education versus being non-employed 1.6 times higher. Both results can be interpreted in the light of Coleman's (1988) theory of social capital where he postulates that social capital in the family plays a role in the creation of human capital in the raising generation. Parent education is also a discerning factor. Having parents with university education made the odds of continuing education versus working 2.0 ($\approx \exp(0.680)$) times, and the odds of continuing education versus being non-employed 1.9 times higher than having parents with secondary education. Again, these results confirm the earlier research. It can be interpreted in the light of

1
2
3
4 inter-generational transmission process and are in accordance with those
5
6
7 of Österberg (2000). Geographical origin mattered in the case of Asians
8
9
10 (continuing education versus working), Middle-Easterns and Africans⁵,
11
12
13 and East-Europeans (transiting to non-employment versus continuing to
14
15
16 higher education). The significance of parental income is at the 10 per-
17
18
19 cent significance limit but when we disaggregated the source of parental
20
21
22 income, father's labour income and welfare income were significant but
23
24
25 affected the odds in the opposite way. Father's labour income increased
26
27
28 the odds of continuing education versus both working and being in non-
29
30
31 employment state whereas welfare income decreased it.

32 [Table 2 about here]

33 34 35 36 **6.2 Transitions after continued education**

37
38
39 Table 3 shows the results of the estimated parameters based on Cox
40
41
42 proportional-hazard gamma-mixture and log-logistic hazard gamma-mixture
43
44
45 models. The results from both models are similar. The signs, as expected
46
47
48 are the same in both models. One can see that having parents with higher
49
50
51 education decreases the hazard of exit from continuing education to work,
52
53
54 to non-employment and to military. This result is somewhat similar to
55
56
57 that of Nielsen *et.al.* (2001), with Danish data, which they interpreted
58
59
60 as a “perverse effect” on the probability of entering the first job after
leaving the educational system. In our case, the original state is contin-

uing education, which one can be viewed in the social-capital framework of the family. Highly-educated parents may motivate their children more or act as role-models.

[Table 3 about here]

Compared to the native Swedes, the hazard of transiting to work was higher for other Nordics, and for Asians, —although not statistically significant— but lower for everybody else, especially the Middle-Easterns, Africans and Latin Americans.

Father's and mother's labour-income similarly decreased the hazard of exit to work, joining the military and transiting to non-employment.

The statistical significance of the unobserved heterogeneity-parameter in the parametric case may indicate ethnic discrimination in Sweden since we controlled nearly for all the individual and socioeconomic variables. Hayfron (2001 b) also draws a similar conclusion for Norway when he obtains robust discrimination estimates to the alternative methods he uses in decomposing Norwegian men-immigrant women earnings gap.

6.3 Transitions from non-employment (after compulsory education)

After compulsory education 109 individuals were initially non-employed within a year. Majority of them (70) transited from non-employment to work, while 27 joined the military. The estimated parameters of the

1
2
3
4 transition from non-employment, based on Cox proportional hazard and
5
6 accelerated failure time log-logistic models are reported in Table 4. The
7
8 signs, as expected, are opposites in both models (since one of them esti-
9
10 mates parameters for the hazard, and the other for the waiting time. If
11
12 the hazard is high, then transitions occur quickly and survival times are
13
14 short). Coming from a two-parent family shortened the time in the non-
15
16 employment state; the ratio of estimated hazard of transiting to work
17
18 was 2 ($\approx \exp(0.688)$), controlling for other covariates. The risk of exit
19
20 non-employment state is lower for those from the Middle-East, Latin
21
22 America or Africa. Similar results are found for England and Australia.
23
24 Price (2001) found that recent white and non-white immigrant men ex-
25
26 perience much higher levels of unemployment than earlier cohorts. For
27
28 whites, this effect was transitory, whereas for non-whites unemployment
29
30 rates adjusted more slowly as the duration of stay increased. In con-
31
32 trast to the United States and Canada, Nahid and Shamsuddin (2001)
33
34 observed that the probability of receiving unemployment benefits was
35
36 higher for immigrants than the native born population in Australia. The
37
38 neighbourhood-effect (ethnic concentration) also prolonged the waiting
39
40 time in the non-employment state. Again this result is similar to that of
41
42 Nielsen, et.al. (2001). Cardak and McDonald (2004) found that ethnic
43
44 concentration affected positively in high school completion and university
45
46 enrolment for some immigrant groups in Australia. The neighbourhood-
47
48 effect (ethnic concentration) also prolonged the waiting time in the non-

employment state. Again this result is similar to that of Nielsen, et.al. (2001). Cardak and McDonald (2004) found that ethnic concentration affected positively in high school completion and university enrolment for some immigrant groups in Australia. Having at least one Swedish parent reduced the waiting time and increased the hazard of transiting to military.

[Table 4 about here]

One of the important variables in the study of first generation immigrants' transitions from non-employment into work is language proficiency. Although it was not measured directly for immigrants in the LINDA data set, we can assume that language proficiency was sufficient for the second-generation immigrants in Sweden. Using data from the Fourth National Survey of Ethnic Minorities, Shields and Price (2001) investigated the determinants of location-specific language capital and its impact upon the employment prospects of male and female ethnic minority immigrants in Britain and found that lack of English language fluency reduced average predicted employment probabilities by 20-25 percentage points. Contrary to expectation, Hayfron (2001 a) found that language proficiency had no significant effect on immigrants' earnings when he studied the relationship between language training, language proficiency and earnings of immigrants in Norway. A probable explanation might be that immigrants needed Norwegian language proficiency to get into jobs

1
2
3
4 in the Norwegian labour market. Once they were in employment, their
5
6 wages were not necessarily determined by their proficiency in Norwegian.
7
8
9

10 11 **6.4 Transitions from non-employment to work (af-** 12 13 **ter continued education)** 14 15

16
17 The estimated parameters of the transitions from non-employment after
18 continuing education to work, based on Cox proportional-hazard gamma-
19 mixture and Log-logistic gamma-mixture specifications are reported in
20 Table 5.
21
22
23
24
25

26
27 The results are very robust for both specifications. Parents with more
28 education again seem to have children who are more likely to transit to
29 work faster. On the other hand, those from Africa, Middle-East or Latin
30 America were considerably less likely to exit to work. This was also found
31 by Schröder and Wilhelmsson (1998). The parameter of total parental
32 income was statistically significant (subcategories of income were not)
33 and had a positive effect the hazard of transiting to work.

7 Summary and conclusions

We have analysed the early labour-market experiences of second-generation immigrants in Sweden. A register based data set (LINDA) containing information on 1106 16-17 year-old second-generation immigrants and a statistical twin sample of Swedes as a control group in terms of age and region (also 1106 individuals) were followed for the period 1991-2000. Four types of labour-market outcomes were studied: Transitions after compulsory education; after continued education; and from non-employment after compulsory education and after continued education.

The alternative models used showed similar results:

- Parental resources; marital-status, education, occupation, and income, are not only affecting second-generation immigrants' continued education but also their labour-market success. For all young people, regardless of their ethnical backgrounds, parental capital in the form of parents' attained education, occupation and income is vital. Inter-generational transmission channels are thus still important, contrary to what we expected for Sweden.

- Even after controlling for numerous individual, parental, socio-economic variables, geographical origin was a major labour-market hindrance for second-generation immigrants from Africa, Middle-East and Latin America.

- The significance of an unobserved-heterogeneity parameter may indicate discrimination.

As a whole, second-generation immigrants have worse labour-market performances than their native-born counterparts. They have weaker chances for an economic catch-up and thus show a slow economic integration with persistent earning-differentials. Our conclusions give therefore a strong support to the Borjas' North-American results of a long integration process of immigrants.

7.1 Policy implications

The evidences found in this study therefore raise some policy implications. First, social class differences persist across generations regardless of parent's ethnical backgrounds. The children of parents who have low-income status and weak labour-market attachment have difficulties to enter successfully into labour market. An increase in the economic income status and an improvement of the labour market attachment of the low-income families will also lead to a progress of their children's entry into labour market. In this sense, there is a need for policies to achieve a more equal income distribution in the society in the long run.

Second, the low probabilities of finding a job for second-generation immigrants, especially for those coming from Africa, Latin America and Middle East require some origin country-specific arrangements, such as giving specific information to these groups or arranging special campaigns for them in the short run.

Third, political measures against discrimination of immigrants in the

1
2
3
4 labour market in general can be improved. This situation also requires
5
6
7 some specific policies against discrimination of immigrants together with
8
9
10 policies against traditional prejudices of women and ethnic groups in the
11
12 society, in general.
13

14 In another companion paper, Tasiran and Tezic (2006), we suggested
15
16 policy changes similar to above when we studied the effects of parental
17
18 income on the continuing education of second-generation Immigrants in
19
20 Sweden.

54
55
56
57 The problem of unobserved heterogeneity, or the bias caused by not
58 being able to include particular important explanatory variables has a
59
60

larger impact in transition data models than in other types of regression models. Unobserved heterogeneity may introduce, among other things, downward bias in the duration effects, spurious effects of time-varying covariates, spurious time-covariate interaction effects, and dependence among competing risks and repeatable events. For transition data models testing for unobserved heterogeneity was a complex problem. A feasible approach was suggested by Lancaster (1984) and it is based in the information matrix (IM) test introduced by White (1982).

In a duration model, T be a random variable with probability density function

$$f(t \mid \theta_0, \theta_1), \quad (14)$$

where θ_0 is a scalar and θ_1 a vector of parameters. Let

$$g(\nu \mid \sigma^2), \quad (15)$$

be the probability density function of a random scalar variable V with mean zero and variance σ^2 . Now consider the more general model for T with probability density function

$$f(t \mid \theta_0, \sigma^2, \theta_1) = \int_{\nu} f(t \mid \theta + \nu, \theta_1) g(\nu \mid \sigma^2) d\nu. \quad (16)$$

The parameter θ_0 that was fixed in the null model has in the generalized model with mean θ_0 and variance σ^2 . To test the model we can do a score test of the null hypothesis $\sigma^2 = 0$ against the alternative hypothesis

$\sigma^2 > 0$.

It has shown that for a large, flexible class of distributions $g(\cdot)$, and for a general choices of models $f(\cdot)$, the score function that is the basis of score test for testing the null that $\sigma^2 = 0$, is proportional to

$$\left[\frac{\partial \ln f}{\partial \theta}(t; \theta_0, \theta_1) \right]^2 + \frac{\partial^2 \ln f}{\partial \theta^2}(t; \theta_0, \theta_1). \quad (17)$$

which has expectation zero by the information matrix equality.⁶

Lancaster (1984) suggested a simple way to carry such tests. Under the null hypothesis this test statistic has a chi-squared distribution. Blossfeld, Hamarle and Mayer (1989) used a version of the same test statistic that had a normal distribution. The test statistic can be written

$$\tau = \frac{1}{2n} \sum_{i=1}^n \left[H^2(t_i | \mathbf{x}_i; \hat{\theta}) - 2\delta_i H(t_i | \mathbf{x}_i; \hat{\theta}) \right] \quad (18)$$

where $H(t_i | \mathbf{x}_i; \hat{\theta})$ are the maximum likelihood estimates of the integrated hazards for the model without heterogeneity and δ_i is the censoring indicator with $\delta_i = 1$ for uncensored and $\delta_i = 0$ censored observations. We report the values of this test statistic below. The results indicate that the assumption of unobserved heterogeneity holds for these transitions.

Transition from continuing school to work: 4.49

Transition from continuing school to non-employment: 5.27

Transition from continuing school to military service: 4.50

Transition from non-employment after continuing school to work:

2.16

ENDNOTES

¹ The log-logistic hazard function is $h(t) = \frac{\gamma\lambda(\gamma t)^{\gamma-1}}{1+(\gamma t)^\gamma}$ where $\lambda = \exp[-(\beta_0 + \beta_2 x_2 + \dots + \beta_k x_k)]$

and the corresponding density function is

$$f(t) = \frac{\lambda^{\frac{1}{\gamma}} t^{\frac{1}{\gamma}-1}}{\gamma(1+(\lambda t)^{\frac{1}{\gamma}})^2}$$

² When there were many ties, we used the approximation method proposed by Efron (1977).

³ The observed log-logistic hazard with gamma mixture specification becomes

$h(t) = \frac{\lambda\gamma(\lambda t)^{\gamma-1}}{1+(\lambda t)^\gamma} [1 + \delta \log(1 + (\lambda t)^\gamma)]^{-1}$ where δ is the variance of the mixing gamma distribution.

⁴ Between two contrasts, reversing the reference category causes reversing the sign.

⁵ We put Middle-Easterns and Africans in the same category since Middle-Easterns did not transit to working state.

⁶ The score function has expectation zero at the true values of the parameters.

$$E \left[\frac{\partial \ln f}{\partial \theta}(t, \theta_0) \right] = 0.$$

It is based on the Information Matrix Equality and says that

$$I(\theta_0) = -E \left[\frac{\partial^2 \ln f}{\partial \theta \partial \theta'}(t, \theta_0) \right] = E \left[\frac{\partial \ln f}{\partial \theta}(t, \theta_0) \cdot \frac{\partial \ln f}{\partial \theta}(t, \theta_0)' \right]. \quad (19)$$

Note that this equality only holds at the true values of parameters.

Numbers on the power of coefficients, are not powers, they indicate p-values in percents,

i.e power 6 means p-value between 0.05 and 0.06...so on.

The reference variables included in the constant are: female, one-parent family, no Swedish parent, secondary education, and Swedish.

^{a,b} “male” and “at least one Swedish parent” were omitted when we focused on the transition to the military, since all who joined military were male and almost all had at least one Swedish parent.

As before, the reference variables included in the constant are: female, one-parental family, no Swedish parent, secondary education, and Swedish.

^aAs in the previous outcome, Individual variable being male is omitted when we focused on the transition to military, since all of the individuals who made transition to military were male.

^b Due to the small number of observations, those from the Middle-East, Africa, and Latin America were combined as one group with all others as the reference group. As before, The reference variables included in the constant are: female, one-parental family, no Swedish parent, and secondary education.
